The theory of the SdH effect is complicated since it involves the problem of electron scattering in a magnetic field. In 1959, E N Adams and T D Holstein calculated the oscillatory conductivity for two different scattering mechanisms and found similar results in both cases. They concluded that the exact nature of scattering is not very crucial. Their result for the case of phonon scattering and high quantum number is the following:

$$\frac{\tilde{\sigma}}{\sigma} = \frac{R_T \frac{5}{2} \tilde{N}}{N_0}$$

where $\tilde{\sigma}$ is the oscillatory part of the conductivity, σ the steady conductivity, R_T the temperature reduction factor and $\tilde{N}, N_0$ are the oscillating and steady parts of the density of states at the Fermi energy, respectively. This result can be understood qualitatively by an argument of Pippard: the probability of scattering is proportional to the number of states in which the electrons can be scattered. Therefore, the conductivity is related to the oscillations of the density of states. The SdH effect is described by the same reduction factors as the dHvA effect. R_S and R_D are already involved in $\tilde{N}$. Finally, one should mention that the oscillatory part of the density of states and thus the oscillatory conductivity is proportional to the derivative of the magnetization dM/dB .

Two-Dimensional Case

The above mentioned theories for the dHvA and SdH effect were calculated for an isotropic case, that is, for a spherical Fermi surface. It turned out that they can also describe anisotropic systems with ellipsoidal or even warped cylindrical Fermi surfaces well. But in the pure 2D case, the theory is no longer applicable. From a theoretical point of view, it turned out that the 2D case is in some respect more difficult to calculate than the 3D one, and up to now, analytic solutions are available only for limiting cases.

Typical examples for Q2D electron systems are layered metallic compounds. The energy spectrum is usually given by

$$E_k = \frac{\hbar^2}{2m} (k_x^2 + k_y^2) - 2t \cos(k_z d)$$

with t being the interlayer transfer integral, k_z the wave vector perpendicular to the layers, and d the interlayer distance. This yields a cylindrical Fermi surface with a slightly oscillating cross section along the k_z direction (warping). In the case of $2t > \hbar\omega_c$, the system can be well described within the LK theory. In that case, there exists a minimal and a maximal cyclotron orbit and one expects two nearby frequency components in the dHvA spectrum (see Figure 4).

When the transfer integral becomes comparable to the Landau level separation, the LK theory is no longer appropriate and for $2t < \hbar\omega_c$ the system is very near to the pure 2D case. In that case, the whole Fermi surface is extremal and one expects large oscillations. It is also clear that the assumption of a field independent chemical potential is, generally speaking, no longer valid. For a constant number of electrons, one would rather expect jumps in the chemical potential periodic in $1/B$. In the extreme 2D case, the Fermi energy lies between two Landau levels. The chemical potential is fixed to the highest occupied Landau level and when this level is depopulated by increasing the field, the chemical potential will jump to the next lower Landau level. A sawtooth form of the magnetization oscillations is expected for that case and was indeed observed in artificially grown 2D electron gases. The other limiting case of a fixed chemical potential can be fulfilled by oscillations of the total number of electrons due to an infinite reservoir. This situation is probably given in some organic metals where a Q1D band is present beside the 2D one.

Analysis of Data

In a typical experimental investigation of the quantum oscillations, the first quantity to derive is the oscillation frequency. The oscillatory signal measured in a certain interval of the magnetic field and plotted against $1/B$ is transformed by a Fourier transformation into a power spectrum. This gives the frequencies of the different extremal orbits of the Fermi surface and – if present – their higher harmonics. Repeating this procedure for different field directions allows one to reproduce the complete Fermi surface. One should mention that the frequency only gives the cross section of the extremal orbit, but cannot show the deviations from a circular form.

A comparison with the LK theory gives further information. If the oscillation amplitude is measured at different temperatures, a least-square fit of the temperature reduction factor to the experimental data directly yields the effective cyclotron mass m of this extremal orbit. The magnetic field dependence of the oscillation amplitude at constant temperature is given by the product of the Dingle factor R_D and B^n , where n depends on the experimental method. Knowing the effective mass m from the temperature dependence, one can extract the Dingle temperature by a least-square fit of the field dependence.

Figure 4 Slightly warped cylindrical Fermi surface (black dashed line) of a Q2D metal with Landau cylinders. The magnetic field is applied perpendicular to the conducting plane.

Finally, the spin reduction factor R_s can be used to determine the spin-splitting factor g . In most cases, there is an intrinsic ambiguity in the determination of the g -factor and only a series of possible values can be derived. A special situation is given in the layered organic metals. Due to the relatively high effective mass m and the angular dependence of m , usually a whole series of angles appears, where the oscillation amplitude vanishes due to R_s . This allows one to determine the product gm/m_e without ambiguity.

Special Cases

Magnetic Interaction, Condon Domains

Normally, the oscillating part of the magnetization $\mu_0 \tilde{M}$ is much smaller than the applied magnetic field B_a . Therefore, in the LK theory the inner magnetic field B_i was taken as the applied field B_a . In some cases (very pure metals with large Fermi surfaces, low temperature), this assumption is no longer valid as was first observed by Shoenberg in very pure samples of gold. To analyse his data, he started with the LK-equation for the first harmonic and replaced B by B_i . He could show that the condition

$$a = \mu_0 \left| \frac{d\tilde{M}}{dB} \right| < 1$$

must be fulfilled for the LK theory to be fully applicable. If the factor a is smaller than 1 but of the same order of magnitude, the observed oscillations show an increased harmonic content and, if several different orbits are involved, the occurrence of combination frequencies is expected. In these cases, one has to take into account the demagnetization factor n of the sample shape also.

If the factor a becomes larger than 1, the magnetization of the sample is no longer a single-valued quantity of the applied field. This is thermodynamically unstable and leads to jumps in the magnetization. As first proposed by Condon, under this condition a sample with a demagnetization factor $n > 0$ will split up into magnetic domains with two different values of the magnetization. The existence of these domains could be shown by NMR and muon spin rotation experiments. Up to now, clear evidences for Condon domains are reported in high-quality samples of silver, beryllium, white tin, aluminum, and lead.

Magnetic Breakdown and Quantum Interference

The Fermi surface of a metal can be completely described within the first Brillouin zone. Any constant energy surface exceeding this zone belongs to higher bands and can be folded back to the first Brillouin zone. It was therefore very exciting, when in the beginning

of the 1960s, Priestly reported the observation of a dHvA orbit in Mg, which was considerably larger than the hexagonal cross section of the Brillouin zone. The explanation for this observation was given by Cohen and Falicov, who pointed out that electrons could tunnel from one band to another, if the bandgap E_g between these two bands is sufficiently small and the magnetic field strong enough. It is evident that this could happen, when the bandgap is comparable to or smaller than the Landau level separation $\hbar\omega_c$, but Blount could show that the much weaker condition

$$\hbar\omega_c \geq \frac{E_g^2}{E_F}$$

is valid, with E_F being the Fermi energy. Since typically $E_g/E_F < 1$, magnetic breakdown could happen in quite low magnetic fields.

For the theoretical description of magnetic breakdown, a simple hypothetical model of a free electron gas in a 1D crystal potential was introduced as shown in Figure 5. At the zone boundary, a small gap opens and the Fermi surface consists of a closed (α -orbit) and an open part. At very high magnetic fields, electrons can tunnel through the gap and a new much larger closed orbit (β -orbit) is observed. At intermediate magnetic fields, a complicated spectrum with sum and difference frequencies of α - and β -orbits will appear. The case – first thought as hypothetical – was in the meantime verified in artificial heterostructures and in organic metals such as $(\text{BEDT-TTF})_2\text{Cu}(\text{NCS})_2$ and is of high interest at present.

In systems, where magnetic breakdown is present, one often finds a striking difference in the frequency spectrum of dHvA and SdH oscillations. The SdH oscillations typically show additional frequencies not present in dHvA. These differences can often be described by quantum interference effects as introduced first by R W Stark and C B Friedberg: it is possible to have magnetic breakdown between orbits, along which electrons move in the same direction; if electrons moving from point A to B can travel along two different paths connected by magnetic breakdown, interference effects yield an oscillatory contribution in transport measurements with the frequency determined by the area between the two paths. Since this represents not a closed orbit, these frequencies are not detected in thermodynamic quantities such as dHvA oscillations.

Experimental Techniques

Orders of Magnitude

Quantum oscillations are periodic in the reciprocal magnetic field. Therefore, the unit of the oscillation frequency is tesla (T). Typical values range from a few T to ~ 50000 T. Low-frequency oscillations are easier to detect and can be often observed up to temperatures of 10–20 K. The observation of high-frequency oscillations requires usually low temperatures ($T < 4$ K), and high and homogeneous magnetic fields. (The oscillation period of a 50 kT frequency amounts to $20 \mu\text{T}$ at $B = 1$ T.) The observation of oscillations in the heavy fermion compounds needs dilution fridge temperatures for detection. This can be easily verified by calculation of the temperature reduction factor R_T with high effective cyclotron masses.

Optimal relative amplitudes of the oscillatory magnetization $\mu_0 M/B$ are $\sim 10^{-5}$, which is comparable to steady susceptibilities of weakly magnetic materials. The sensitivity of magnetization experiments is often improved by measuring dM/dB (see below). The oscillations in the resistivity are experimentally observed mainly in semimetals and under magnetic breakdown conditions. In recent years, the SdH effect plays an important role in layered metals and quantum well structures. In both cases, the oscillatory amplitude can exceed the background resistance in high magnetic field considerably.

Figure 5 Model Fermi surface for magnetic breakdown: at small fields the carriers are fixed to the closed α -orbit or the open orbit above and below, at high magnetic fields the carriers can tunnel through the gap and a larger closed orbit (β -orbit, dashed line) becomes dominant.

Magnetic fields are typically produced nowadays by superconducting magnets. The maximum field available in laboratories lies between 8 and 20 T. Higher steady magnetic fields can be obtained in some high-field magnet laboratories running high-power (typically, 10–25 MW)-resistive or superconducting-resistive hybrid magnets. These laboratories are usually open for users and can offer magnetic fields between 20 and 45 T. For even higher magnetic fields, some pulsed field facilities are operated. For the study of metallic samples, they can produce magnetic field pulses of duration between a few ms and 1–2 s with maximal fields between 35 and 70 T.

de Haas–van Alphen Techniques

The above mentioned magnitude of the oscillatory effect shows that the standard techniques for measuring small magnetic susceptibilities are often sufficient for the observation of the dHvA effect. But for observation in less favorable circumstances, techniques with very high sensitivity are needed. It should also be mentioned that the high degree of field homogeneity required for the observation of high-frequency oscillations makes the Faraday method less suitable. The two mostly used methods are discussed in the following.

Pickup coil techniques

This technique is similar to the well-known mutual inductance method for AC-susceptibility measurements. The sample is placed in a pickup coil system consisting of two identical coils connected in series with opposite signs so that the voltage induced by a changing magnetic field is zero. If a sample is placed in one of the coils, the induced voltage will be

$$U \propto (dM/dB)(dB/dt)$$

The proportionality constant is determined by the geometry. For the arrangement of the two balanced coils, many possibilities exist. Due to limited space of high homogeneity in a magnet, the two coils are often wound one after the other on the same coil core. In the standard laboratory method, the applied magnetic field B is superimposed by an oscillatory contribution $b(t) = b_0 \cos(\omega t)$, with typical frequencies ω lying between 20 Hz and a few kHz. The oscillation amplitude b_0 can be appropriately chosen for the system under consideration. It should be smaller or comparable to the period of the dHvA oscillation. The modulation field method allows the use of phase-sensitive detection via lock-in amplifiers, which considerably improves the signal-to-noise ratio. In addition, this allows detection at different harmonics of the modulation frequency.

The signal amplitude of the different harmonic contributions A_p of the LK theory is given by

$$U_p^{(k)} \propto k \omega J_k \left(\frac{2\pi p F b_0}{B^2} \right) A_p$$

for detection at the k th harmonic of the modulation signal, J_k is the k th order Bessel function. Some disadvantage of this method is the fact that the weight of the harmonics is changed: in case of high harmonic content, the observed waveform deviates from the real one and has to be recalculated. On the other hand, this can be used for suppressing a certain harmonic by working near the corresponding Bessel function zero, and therefore having increased sensitivity for other weak oscillations.

The changing magnetic field may be also produced by a pulsed magnetic field. In that case, the induced voltage is first amplified and then recorded by a fast data acquisition system. In both methods, a self heating of the sample due to eddy currents must be avoided.

Torque method

If the Fermi surface of a given metal deviates from spherical symmetry, that is, if the characteristic frequency F of an extremal orbit is dependent on the field orientation, there exists a torque about any axis perpendicular to the magnetic field given by

$$\tau = -\frac{1}{F} \frac{dF}{d\theta} B V M$$

where, θ determines the angle between the magnetic field B and a characteristic direction in the plane perpendicular to the torque axis, V is the volume of the sample, and M is the parallel magnetization as given by the LK formula. The torque vanishes for some symmetry directions of the crystal, where either $dF/d\theta$ vanishes or two related parts of the Fermi surface cancel each other. In practice this is often not a problem, since the missing angular range is very small and can be easily interpolated. In case of large oscillations, the torque should be measured by a feedback system to avoid problems due to slight changes of the sample orientation (torque interaction). A strong advantage of this method is the robust and easy set-up and the ease of calibrated measurements. Calibrated measurements are of importance for determining the curvature factor of the extremal orbit in the LK formula. A typical example of an oscillatory magnetic torque is shown in Figure 6.

The torque method is one of the first techniques applied by Shoenberg already in 1939, but is still in use in many cases. Whereas the first experiments used the torsion of a wire and optical detection, most of the present devices are based on capacitive detection of the torque. In a simple arrangement, the sample is placed on a small platform on a cantilever. The displacement of the platform is determined by a measurement of the capacitance between the platform and a fixed plate. Adding a calibration coil to the platform allows calibrated measurements. Nowadays, such cantilever spring torque meters can be fabricated from a silicon wafer using lithographic techniques. Miniature devices of this kind were even used in pulsed field experiments.

Figure 6 (a) Magnetic torque oscillations in very high magnetic fields showing magnetic breakdown. The sample is a small ($m=80 \mu\text{g}$) single crystal of the organic Q2D metal κ -(BEDT-TTF) $_2$ Cu(NCS) $_2$. The tilt angle between the direction of magnetic field and the normal to the conducting layers is 40° . (b) Corresponding Fourier transform of the data in (a). The spectrum clearly shows the first and second harmonic of the α -orbit and the breakdown frequency F_β (see Figure 5).

Shubnikov–de Haas Techniques

Measurements of resistance always require a four wire arrangement: a current is applied to the sample via two contacts and the voltage drop between two other contacts is measured. For absolute measurements of the resistivity, the sample should be in a well-defined geometry to assure homogeneous current flow. The application of an AC- current with typical frequencies between 10 and a few hundred Hz allows phase-sensitive detection via a lock-in amplifier. For low-temperature experiments, the current must be small enough to avoid self-heating of the sample.

As mentioned above, the SdH effect is hard to detect in pure metallic elements. At present many SdH studies are carried out in 2D systems. In artificially produced 2D layers, the geometry is easy to adjust by using suitable masks. The typical arrangement is a rectangular bar with current contacts at both short sides and typically two additional contacts on both sides for voltage measurements. This allows one to measure the resistance and Hall effect at the same time. (For the calculation of the conductivity of a pure 2D system, both quantities are needed). In bulk-layered metals the in-plane resistance is often difficult to determine, since the crystals are usually very tiny and the arrangement of well-defined contacts with a homogeneous current distribution is difficult to accomplish. Therefore, most researchers use the interplane resistance for the determination of the SdH effect in these compounds. In that case, a current and a voltage contact are placed on both the large sides of a crystal. Due to very high anisotropy in the resistance (10^3 and more) in these compounds, the interplane resistivity is measured with high accuracy.

Abstract

Core-level photoemission has been and remains one of the most powerful spectroscopic techniques for studying the structure and properties of condensed matter. With the advent of high-resolution instrumentation, for both electron analyzers and photon sources, coupled to large accelerating machines such as synchrotrons, core photoemission spectroscopy (CPS) has revealed its great potential, notably in the study of surfaces and interfaces prepared in ultra-high vacuum.

Through peak fitting procedures, CPS performed on graphene and its first Xene siblings (two-dimensional elemental artificial materials), namely, silicene, we will retrace remarkable discoveries, where core-level photoemission has played a major role.

Introduction

Core photoemission spectroscopy (CPS) is considered as one of the most significant techniques for studying the physical-chemical properties of atoms, molecules and solids, within the general context of the study of matter. Historically, to position the birth of the photoemission phenomenon, it is necessary to go back in time to the distant 1887–1888, with the first experiments performed by Heinrich Hertz (Hertz, 1887) and Wilhelm Hallwachs (Hallwachs, 1888), and successfully explained by Albert Einstein in 1905 upon invoking the quantum nature of light (Einstein, 1905), through his famous formula for the photoelectric effect:

$$E_k = h\nu - |E_B| - \Phi \quad (1)$$

where E_k is the kinetic energy of the photoemitted electron, $h\nu$ is the energy of the incoming photon, E_B , for instance, the one-electron binding energy (BE) of a core-level, and Φ the work function of the emitting material.

Basically, a photoemission experiment is based on the photoelectric effect (Einstein, 1905), where, typically, in condensed matter physics, a solid surface is irradiated by a beam of monochromatic photons, and the kinetic energy of the emitted electrons analyzed.

In the ultraviolet (UV) spectral energy range, of the photons, (10–100) eV, the photoemission spectroscopy is called UPS. With X-ray radiation in the (100–1000) eV range it is called soft X-ray photoemission spectroscopy (SXPS), and, for higher energies it is called XPS or electron spectroscopy for chemical analysis (ESCA). Conventional quasi-monochromatic discrete light sources such as

[☆]Change History: March 2023. PD Padova, P Perfetti, GL Lay. All authors changed the title, and according with template, they arranged the reported sections. All authors decided the text. All authors decided the included figures. All figures are new, except the Fig. 2, which is similar to Fig. 1A of the old chapter Core Photoemission, and now is also in color. All sections, now, are different, although the content of the basic photoemission principles, written in another way, are similar.

Fig. 1 Schematic illustration of a photoemission spectroscopy experiment.

Fig. 2 Schematic relation of the energy-level diagram and energy distribution of the photoemitted electrons upon $h\nu$ photon excitation. The solid sample is a metal exhibiting core levels, valence-conduction bands (here, they are the same) and secondary emission in absence of electron-electron interaction. Main line and satellites account for electron-electron interactions.

the helium gas-discharge lamp, for energies in the UV range (He I: 21.23 eV; He II: 40.82 eV), and the characteristic lines emitted by the frequently used aluminum (Al-K α : 1486.6 eV) and magnesium (Mg-K α : 1253.6 eV) anodes, are very often present in laboratories, whereas continuous electromagnetic spectral radiation, from energy of few eV up to thousands eV, is available at the large synchrotron facilities, located in many different countries around the world.

As is simply schematized in Fig. 1, the light (vector potential A), impinging on the surface of a solid sample (or on a liquid or a gas), produces by the photoelectric effect excited electrons, which are collected and analyzed in their kinetic energy, E_K , and momentum p (wave vector $p/\hbar$) in an electrostatic electron energy analyzer.

In an angle-resolved photoemission experiment of solids, interfaces and thin films, the polarization of the light is a useful property, so that the important parameters to be measured are E_K , of the photoemitted electrons, and the angle of emission with respect to the direction of the incident light ($\Psi + \vartheta$) and the surface (ϑ, φ); ϑ , and φ are the polar and azimuth angles, respectively, under which the electrons leave the surface. The binding energy of the outgoing electrons can be obtained by measuring their kinetic energy E_K , and, if knowing the work function of the material, simply by applying Einstein's formula (1). The momentum p is determined by the E_K through the relation $E_K = \frac{p^2}{2m}$ for free electrons.

Let us, briefly, illustrate the relation between the energy levels of a solid and the energy distribution of the photoemitted electrons through of the scheme displayed in Fig. 2, where various contributions, including a core level, are highlighted. In this simple case the sample is a metal, therefore its Fermi energy E_F lies at the top of the occupied states within the valence-conduction band (VB/CB). E_F is separated from the vacuum energy level E_{vac} by the metal work function ϕ .

When the photoabsorption process takes place in a core level with a binding energy E_B ($E_B = 0$ at E_F), photoelectrons with kinetic energy given by the formula (1), can be detected in the vacuum, giving rise to the CLS (core level photoemission) process. The

energy distribution of the photoemitted electrons, i.e., their number $N(E)$ per energy interval, corresponds, as a first approximation, to a replica of the electron energy distribution in the solid.

This is a real crucial point in photoemission spectroscopy, since it interestingly provides the features of the energy distribution of electrons in a material.

We present in this article diverse applications of core photoemission spectroscopy in the current investigations of 2D elemental materials, typically, graphene and silicene. Their study constitutes, nowadays, one of the most interesting topics in condensed matter physics and chemistry.

Overview of core photoemission spectroscopy

For a fundamental and exhaustive theoretical treatment of the photoemission process, we refer to important literature (Cardona and Ley, 1978; De Padova and Perfetti, 2005; Feuerbacher et al., 1978; Hüfner, 2003). Here, we just report the basic principles for fully understanding the power of this old, but unique, spectroscopic technique, as well as for conducting and/or analyzing a photoemission experiment in the context of condensed matter with particular emphasis on the investigation of graphene and silicene on well-characterized surfaces.

Photoemission spectroscopy (PES) investigates the occupied valence/conduction electronic bulk and surface states of materials, as well as their localized core-levels, which are fingerprints of their constitutive atomic species. Hence, core-level photoemission spectroscopy, which highlights the elementary atomic specificity of matter, constitutes an irreplaceable tool for the investigation of the physical-chemical properties in materials science.

It is convenient to consider the so-called *sudden-approximation*, to understand the transition probabilities from an occupied state to an empty state promoted by a photoemission process, regulated by the Fermi "golden-rule," when the Hamiltonian changes so rapidly that the reaction times of the system in its entirety, are too short to cause relaxation effects, which would lead to observable perturbations in the photoemission spectra. In PES a system with N electrons in the initial state, is left after one-electron excitation in a final state containing $N-1$ electrons and a hole, such that the energy of the outgoing electron is usually affected by the interaction of the surrounding ionized system that has been left behind. If this interaction is negligible (in the regime of *sudden-approximation*) and the photoelectron kinetic energy, E_k , is high enough, it can be derived directly by the Einstein relation (1). In the one-electron approximation, it is assumed that the $N-1$ electrons of the orbitals will be in the same final state $\langle f |$ as in the initial state $| i \rangle$, under the so-called "frozen-orbital approximation."

In general, in a CPS process, the probed photocurrent is expressed through the representative relation:

$$I \propto \sum_{f, i, k} | \langle \phi_{f,Ek} | \mathbf{r} | \phi_{i,k} \rangle |^2 \sum_s | c_s |^2 \delta (E_{f,k} + E_s (N-1) - E_0 (N) - h\nu), \quad (2)$$

where it is supposed that the final state with $N-1$ electrons possesses s excited states with energy $E_s(N-1)$; E_0 is the ground energy state of the N electrons, and $E_{f,k}$ is the kinetic energy of the photoelectron promoted from the initial state $|\phi_{i,k}\rangle$ to the final state $\langle \phi_{f,Ek} |$, while $|c_s|^2$ is the probability that the removal of one electron from the ground-state orbital $|\phi_{i,k}\rangle$, is followed by the excitation of s states in the $N-1$ electron system. The Dirac delta function in relation (2) ensures the energy conservation in the transition of the electron from its initial state to the final one, leading, in addition to the "main-line," also to a certain number of possible "satellite-peaks," sometimes called "shake-up lines," which derive from the excitations induced by the interaction of the remaining photo-ionized system with the potential that arises after the creation of a core-hole. This is especially true when a strong interaction occurs between electrons and the core-hole potential, since the charge density of the *valence* electrons would be affected, eventually rearranged, placing the system in an excited state. As a consequence, the core binding energy appears at higher E_B , (*main-line*), and new features take place at lower binding energy (*satellite-peaks*). A very well-established case concerns metallic Ni, where the $3d$, $3s$, and the $2p$ ($2p_{3/2}$ and $2p_{1/2}$ doublet) core levels, are affected (Hüfner and Wertheim, 1975).

Very useful in the interpretation of photoemission spectra is the so-called "three-step model," where the intensity of the photocurrent measured with an electron energy analyzer is considered to result from three independent processes: (i) the optical excitation of an electron considered as a pure bulk transition between an initial and a final Bloch state of the crystal; (ii) the propagation of the excited electron toward the surface; and (iii) the escape of the electron from the solid into the vacuum (De Padova and Perfetti, 2005; Feuerbacher et al., 1978; Hüfner, 2003).

Key issues on core photoemission spectroscopy and its application to important examples, namely the elemental two-dimensional (2D) materials graphene and kagome silicene

Some qualitative information on the nature of a PES spectrum can be obtained, without any calculations, considering that there is a noticeable difference between valence and core levels spectra. Actually, the binding energy of a core level is independent of the exciting wave vector, due to the localization of its core wave function.

This leads to consider a core photoemission spectrum in the simplest way, where the measured peak is constituted by a Voigt function (the convolution between a Gaussian and a Lorentzian function). Their σ_C and Γ_L widths, representing, the overall broadening (especially instrumental and phonon broadening) and the inverse of the core-hole state lifetime, respectively.

However, a number of fundamental effects have to be taken into account in the interpretation of CPS, since they can significantly affect the core level spectrum.

These are initial-state effects ΔE_0 , and final-state effects, ΔE_f . If we define the binding energy E_B of a core level as the difference between the total energy of the non-perturbed state of N electrons in its fundamental state as $E_0(N)$, and the energy of the state formed by the hole and the $N-1$ electrons remaining after the photoexcitation process as $E_f(N-1)$, then $E_B = E_f(N-1) - E_0(N)$.

By defining ΔE_B as the difference between the measured binding energy and the binding energy of an electron in its fundamental state in an isolated atom, then $\Delta E_B = \Delta E_0 + \Delta E_f$.

The physical meaning of these two separate contributions is at the heart of CPS.

Initial-state effects ΔE_0 on the core electron binding energy E_B are mainly due to a change in the electrostatic interactions, between the core electrons and those of the outer shells, determined by the variations in charge distribution. Three fundamental contributions can affect ΔE_0 : (i) the charge transfer upon formation of chemical bonds for the same atomic species in different compounds; (ii) the atomic arrangement, where an atom can be isolated, be in a molecule or solid, or sit at a surface with different bulk and surface configurations (causing either bond charge transfer or valence-electron distribution changes); (iii) the “*Madelung contribution*,” especially present in ionic compounds, related to the charge transfer between the emitter atom and its neighbor ones. The surface atoms that experience a reconstruction and/or a charge transfer give rise to a binding energy shift, named surface core-level shift (SCLS), while the binding energy changes between two different chemical compounds of the same atom is called “chemical shift.”

Final-state effects ΔE_f are associated with the electrons of the outer shells, which “feel” a higher charge of the nucleus, due to the creation of a hole. They relax, by decreasing both the total final energy and the photoelectron binding energy. In the Koopmans’ approximation, the photoelectron binding energy is that of the orbital from which it was removed, considering the relaxation energy of the remaining electrons during the photoemission process negligible and, therefore, $\Delta E_f = 0$.

Intra-atomic relaxation is typical of isolated atoms, not depending on the atoms surrounding the emitter. Examples of this mechanism are the appearances in the photoemission spectra of the above mentioned “*shake-up lines*.”

Extra-atomic relaxation concerns the effects of the relaxation energy of valence electrons on the binding energy of the excited atom core orbital. This effect can be strongly influenced by the type of chemical bond the emitter atom forms with the surrounding atoms. The binding energy shift, thus, depends on the effective screening capacity of the hole induced by the relaxing electrons. For s and p electrons this shift is expected to be higher than for the more localized d electrons.

In metals the relaxation process is often due to electron-hole pair excitations at the Fermi level, leading to a typical asymmetric core lineshape at the lower kinetic energy side. It can be also due to the creation of bulk and/or surface plasmons, collective electron oscillations upon the ions lattice potential. In the first case, the curve that represents the core level lineshape best in the fitting procedure is the Doniach-Sunjić function. In the photoemission process, this can be defined as an intrinsic phenomenon, to be distinguished from the extrinsic interactions related to scattering events. These scattering events are responsible of the smooth background of secondary electrons, on which the intrinsic primary photoelectron contribution is superimposed. They form a huge structure, monotonically decreasing after its maximum located at ~ 2 eV low kinetic energy.

The core-level lineshape in CPS can be affected by various contributions. The intrinsic core-hole lifetime is related to its recombination time through the Lorentzian width.

According to the Heisenberg uncertainty principle, the shorter the recombination time, the greater the uncertainty with which the energy of the emitted core electron is known. Recombination channels in a solid can be radiative (emission of fluorescence photons), or non-radiative (Auger processes, where electrons characteristic of the atomic species accompany the primary photoemission process). Both processes are responsible for the core-level lifetime. Their cross sections depend on the atomic number Z of the atomic species; the fluorescence channel is dominant at large Z .

A feature to be counted as a final-state effect is linked to the excitation of low-energy phonons, which leads to the phonon broadening of the core-level lineshape. Besides, the instrumental resolution depends mainly on the monochromator and the electron energy analyzer. Typically it is considered as a convolution of two Gaussian contributions and the overall Gaussian width takes this into account.

Finally, a very important issue that needs to be dealt with, is the electron escape depth (typically, in monolayers) versus its kinetic energy (eV), related to the so-called “universal curve” for electrons, and, consequently, the bulk or surface sensitivity. Photo-excited electrons, in a PES experiment, lose energy when travelling toward the surface. Many of them are unable to escape into the vacuum, and, hence, cannot be detected. The probability $S(E_k, x)$ that an electron photoexcited at a distance x from the surface, escapes with kinetic energy E_k , has an exponential dependence, following, in a first approximation the relation $S(E_k, x) \propto \exp. [-x/\lambda(E_k)]$, where $\lambda(E_k)$ is the electron escape depth. The “*universal curve*” traces the escape depth $\lambda(E_k)$ as a function of E_k for numerous materials, establishing the dependence of the emitted electron escape depth with its kinetic energy. $\lambda(E_k)$ can vary from tens of angströms, at very low kinetic energy, to a minimum of ~ 3 Å for $E_k \sim 50$ eV, and then slowly grows again up to ~ 20 – 30 Å at $E_k = 1000$ eV.

At the end of this section, we just briefly mention the importance of thorough core level investigations in photoelectron diffraction, for detailed crystallographic structure determinations (Woodruff and Bradshaw, 1994; Woodruff, 2021).

C 1s and Si 2p core levels of graphene and kagome silicene

This year marks the 75th anniversary of synchrotron light experimentally observed. Since 1946 the physicist Herbert Pollack, at the General Electric Research Laboratory in Schenectady (New York, USA), guided the assembly of a circular accelerator for driving

electrons at relativistic energies. One year later, in 1947, the radiation from electrons, the synchrotron light, obtained by *bremstrahlung*, was visually observed at the General Electric 70-Mev synchrotron (Elder et al., 1947), and rightfully entered in science (Margaritondo, 2022).

Today, it has become an indispensable tool for physics, chemistry, biology, cultural heritage, medicine and many other human science activities, where advance knowledge of materials and fundamental matter requires for scientific answers. Through the ability to continuously tune the photon's energy from UV light to soft and to hard x-rays, its polarization state and high brightness, synchrotron light is a formidable ally in the investigation of CPS.

An interesting aspect offered by synchrotron radiation in the study of core levels is the possibility of highlighting in the CPS spectra the characteristics of the surface features of a solid versus its bulk counterpart, upon considering the dependence of $S(E_k, x)$ of the photoexcited electron as a function of its kinetic energy, by choosing the energy of the impinging photons. Since the surface and the bulk atoms may not be equivalent due to their different physical/chemical environment and/or structural ordering, their contributions may appear at different core-level binding energies. Noteworthy, is that in CPS, these surface/bulk effects can be further enhanced by exploiting the angle Ψ , at which the surface is hit by the photons, and, above all, the angle at which the electrons emitted by the sample are analyzed at the detection angle ϑ . One passes from more bulk-mode to more surface sensitive mode upon changing from normal emission to emission at grazing angles (for the experiment geometry see Fig. 1).

Having described the photoemission process and its use in experiments, is now time to present some applications. The next two paragraphs summarize the main results obtained in CPS on graphene and silicene, the prominent representatives among all elemental 2D materials.

C 1s of graphene on SiC(0001) and Ni(111)

Graphene, a one-atom thick carbon layer, arranged in a honeycomb lattice, is the first natural, sheet obtained by peeling graphite, among the nowadays large family of 2D elemental materials. Graphene is extensively prepared in both its suspended freestanding form, and by epitaxial growth on different supporting substrates. Its pioneers Andre K. Geim and Kostantin Novoselov, were awarded the 2010 Nobel Prize, in physics "for groundbreaking experiments regarding the two-dimensional material graphene."

The substrates most commonly used for the epitaxial growth of graphene are Pt(111) (Otero et al., 2010; Sutter et al., 2009; Vinogradov et al., 2011), Ir(111) (Coraux et al., 2008; N'Diaye et al., 2006, 2008; Vinogradov et al., 2011), Cu(111) (Gao et al., 2010), Ru(0001) (Marchini et al., 2007; Sutter et al., 2008), Rh(111) (Preobrajenski et al., 2008), Ni(111) (Mittendorfer et al., 2011; Park et al., 2019), as well as SiC(0001) (Emtsev et al., 2008), and SiC(111)/Si(111) (Ouerghi et al., 2010). In some ways, they can be defined as more or less weakly or strongly interacting with the graphene overlayer. Among the substrates considered to have a weak interaction one has Ir(111) (Coraux et al., 2008; N'Diaye et al., 2006, 2008; Vinogradov et al., 2011), Cu(111) (Gao et al., 2010), and Pt(111) (Sutter et al., 2009; Otero et al., 2010). On the contrary, Ru(0001) (Sutter et al., 2008; Marchini et al., 2007), Rh(111) (Preobrajenski et al., 2008), and above all Ni(111) (Mittendorfer et al., 2011; Park et al., 2019), SiC(0001) (Emtsev et al., 2008) and SiC(111)/Si(111) (Ouerghi et al., 2010), are recognized as promoting a strong interaction between their surface and the overlying graphene layer.

The C 1s core level is the emblem of the versatile carbon element, capable of hybridizing in various forms, namely sp hybridization favoring 1D linear chain-like configurations, as well as sp^2 and sp^3 hybridizations, which permit 2D planar honeycomb, and 3D tetragonal crystalline structures, respectively. This leads, for example, to a narrow single C 1s core level, located at 284.5 eV BE, in the case of cleaved highly oriented pyrolytic graphite (Sette et al., 1990). Instead, for the clean diamond C(111) surface, which is 2×1 reconstructed (Morar et al., 1986), it leads, in addition to the bulk component actually located at 285.00 eV BE (i.e., higher BE than for graphite), to the appearance of a clear surface component, located at 284.20 eV BE, distinct from the bulk component by 0.8 eV. Thus, a BE difference of 0.5 eV is found for the bulk components of the C 1s core levels, for the sp^2 and sp^3 carbon hybridizations. Instead, for the hydrogen-covered C(111) 2×1 surface, the bulk and surface peaks fall at nearly the same energy, because the outermost carbon atoms, which are bonded to hydrogen, with an electronegativity similar to that of carbon, find themselves, practically, in a bulk-like (1×1) configuration (Morar et al., 1986).

Ultrathin graphite layers (so-called few layer graphene (FLG)), present two different behaviors when grown on each of the two polar surfaces of a SiC single crystal, namely, the Si-terminated and interacting (0001) surface, and the quite-inert C-terminated (000 $\bar{1}$) surface (Emtsev et al., 2008).

In the first case, the growth of the carbon layer exhibits, already from the very beginning, a $(6\sqrt{3} \times 6\sqrt{3})R30^\circ$ graphene-like surface reconstruction, on SiC(0001) (Emtsev et al., 2008). Fig. 3 displays the corresponding C 1s core level (Emtsev et al., 2008).

The interaction between this graphene-like carbon layer with the underlying surface is quite strong giving rise to a structured C 1s core-level as clearly visible on the two spectra of Fig. 3. The strong coupling of some of the C atoms in the $(6\sqrt{3} \times 6\sqrt{3})R30^\circ$ reconstructed layer with the substrate has its signature in the C 1s core level, through the presence of two surface components S1 and S2 at 284.75 eV and 285.55 eV binding energy, respectively, in addition to the SiC bulk component, located at 283.70 eV BE, (Emtsev et al., 2008). Note that the intensity ratio between the two surface components S1:S2 ~ 0.5 , is essentially the same, irrespective of the inelastic mean free path of the photoelectrons, which changes from 2.9 to 4.5 Å, for measurements performed at 350 eV and 510 eV photon energy, respectively. This proves that the C atoms responsible for the two surface components, S1 and S2, are lying in the same plane (Emtsev et al., 2008). S1 was attributed to one-third of the carbon atoms in the surface layer, which strongly interact with the dangling bonds of the underlying SiC(0001) surface. S2, located at higher binding energy, was assigned to the remaining two-thirds, only bound to C atoms within the layer.

Fig. 3 C 1s core-level spectra of the SiC(0001)-($6\sqrt{3} \times 6\sqrt{3}$) $R30^\circ$ reconstruction recorded at 350 eV and 510 eV photon energies. Adapted from Fig. 3 with permission from Emtsev KV, Speck F, Seyller T, and Ley L (2008) Interaction, growth, and ordering of epitaxial graphene on SiC(0001) surfaces: A comparative photoelectron spectroscopy study. *Physical Review B* 77: 155303–155310. Copyright (2008) by the American Physical Society.

In the case of graphene grown on the inert C-terminated SiC(000 $\bar{1}$) surface, the C 1s spectrum exhibits two completely separate peaks, the bulk one and that attributed to graphene located at 284.5 eV (Emtsev et al., 2008), like for the C 1s core-level from cleaved highly oriented pyrolytic graphite (Sette et al., 1990).

Another striking case concerns the single layer of graphene grown on the surface of the clean Ni(111) surface prepared by repeated cycles of Ar⁺ ion sputtering and annealing at $\sim 700^\circ\text{C}$, in an ultra-high vacuum (UHV) chamber. Graphene was grown in C₂H₂ gas at low pressure, about $(1.0\text{--}5.0) \times 10^{-6}$ Torr, keeping the sample at $\sim 700^\circ\text{C}$ (Park et al., 2019).

Fig. 4 shows the corresponding C 1s spectra is acquired with synchrotron radiation at 360 eV photon energy. Two different peaks related to C in graphene, directly grown on the Ni(111) surface, and after Au intercalation, are clearly distinguished (Park et al., 2019).

Fig. 4 C 1s core level spectra recorded at 360 eV photon energy from a graphene/Ni(111) interface (red-line), and after gold intercalation (blue-line; graphene/Au/Ni(111)). Adapted from Fig. 1 of Park Y, Jung D, Hwang H-N, Hwang C-C (2019) Electronic structure of the Au-intercalated graphene/Ni(111) surface. *Current Applied Physics* 19: 215–218. Copyright (2018), with permission from Elsevier.

As can be observed, in the first case the C 1s peak is located at ~ 284.8 eV and broadened because of the presence of unresolved components, due to the interaction between the carbon and nickel atoms. Conversely, the C 1s spectrum acquired when Au atoms are intercalated below the graphene sheet reflects its disconnection from the nickel substrate. This narrow peak (blue-line) is shifted toward lower binding energy by ~ 0.50 eV. The C 1s full width at half maximum (FWHM) is ~ 0.84 eV in the first case, and markedly less ~ 0.58 eV, in the second case, indicating the restoration of the graphene sublattice symmetry (Park et al., 2019). Note that, in this last case, the electronic properties of graphene, including the characteristic Dirac cone, are regained, demonstrating simultaneously the absence of interaction with the Au intercalated atoms and the loss of the interaction with the nickel surface (Park et al., 2019).

Si 2p and Al 2p core-levels from $(\sqrt{3} \times \sqrt{3})/(3 \times 3)$ kagome silicene on an Al(111) substrate

The first trans-graphene artificial elemental 2D materials is called silicene. It is a new allotropic form of silicon, constituted of one sheet of Si atoms arranged in a honeycomb (but buckled) lattice, similarly to graphene (Feng et al., 2012; Lin et al., 2012; Vogt et al., 2012). The possible existence of silicene was theoretically predicted (Takeda and Shiraishi, 1994; Guzmán-Verri and Lew Yan Voon, 2007; Lebègue and Eriksson, 2009; Cahangirov et al., 2009), and experimentally realized for the first time in 2012 on a silver single crystal (111) surface, where a 3×3 reconstructed silicene overlayer epitaxially matched a Ag(111) 4×4 supercell (in short named $(3 \times 3)/(4 \times 4)$ reconstruction) (Vogt et al., 2012). Soon after, silicene was subsequently synthesized on different substrates (Fleurence et al., 2012; Meng et al., 2013; Stępniań-Dybala and Krawiec, 2019). Interestingly, the linear dispersions at the high symmetry K/K' points of the surface Brillouin zone (SBZ) and after band folding have been revealed (Avila et al., 2013; Du et al., 2014; Feng et al., 2012, 2016; Lin et al., 2012; Meng et al., 2013; Tsoutsou et al., 2013; Vogt et al., 2012; Davila and Le Lay, 2022).

Strikingly, silicon can form amazing 2D structures showing its versatility, as can be ascertained after the discovery of an exotic kagome structure of silicene, where Si atoms arrange in a large superstructure.

Kagome-like silicene was recently synthesized on aluminum (111) substrates at room temperature (RT) (Sassa et al., 2020). Evidence of such an exotic 2D Si allotrope was given through low energy electron diffraction, scanning tunneling microscopy observations, high-resolution core-level, and angle-resolved photoelectron spectroscopy measurements, along with density functional theory calculations (Sassa et al., 2020). Kagome-silicene is $(\sqrt{3} \times \sqrt{3})$ reconstructed, epitaxially matching an Al(111) (3×3) supercell (in short $(\sqrt{3} \times \sqrt{3})/(3 \times 3)$).

Impressive corresponding Si 2p and Al 2p core-levels are shown in Fig. 5A and B, in both bulk- and surface-sensitive conditions. By a simple visual observation of these spectra, it is possible to get numerous information, directly obtainable from the core photoemission process.

Fig. 5 Si 2p and Al 2p core-level spectra from kagome silicene synthesized on an Al(111) surface, obtained with synchrotron at 136 eV photon energy, in normal (A) and 60° off-normal (B) emission; (C) is the deconvolution of the Si 2p core-level in normal emission (A). Experimental data (black dots); fit curve (solid red line) with the DB1, DB2, DB3 and DB4 doublets. Adapted from Fig. 3 of Sassa Y, Johansson FOL, Lindblad A, Yazdi MG, Simonov K, Weissenrieder J, Muntwiler M, Iyikanat F, Sahin H, Angot T, Salomon E, Le Lay G (2020) Kagome-like silicene: A novel exotic form of two-dimensional epitaxial Silicon. *Applied Surface Science* 530: 147195.

Firstly, the Si 2*p* core level comprises several components associated to different adsorption sites on the Al surface. Secondly, upon passing from bulk to surface conditions, it is clear that all silicon atoms lie on top of the aluminum surface. Indeed, all Si 2*p* structures are enhanced in intensity with respect to the Al 2*p* peak intensity in surface-sensitive conditions, evidencing the surface location of all silicon sites (Sassa et al., 2020).

A thorough analysis was further performed through a least-square fitting procedure, as shown in Fig. 5C, with four components DB1, DB2, DB3 and DB4, lying on a Shirley background (continuous black line) (Sassa et al., 2020). Each component is a doublet (DB) with a spin-orbit splitting of $\sim 600 \pm 10$ meV and a branching ratio of 0.50. Each doublet was built using two Voigt functions with a full width at half maximum (FWHM) of 170 ± 30 meV for DB1 and 285 ± 30 meV for DB2, DB3 and DB4 (Sassa et al., 2020).

Having presented and discussed several remarkable results, it is worth emphasizing at the end of this section that core level photoemission spectroscopy is an extremely powerful investigation tool, which makes it possible to discriminate even just slightly different chemical, physical, and crystallographic environments of specific atomic entities.

Conclusion

This chapter offers a broad overview on core photoemission spectroscopy. For a complete fundamental theoretical treatment of the photoemission process, the reader is referred to specialized texts such as those cited in Refs. (Cardona and Ley, 1978; Feuerbacher et al., 1978; Hüfner, 2003).

Here, we have given the basics by way of striking examples, namely graphene on silicon carbide and nickel, as well as kagome silicene on aluminum. The measurement of the C 1*s*, Si 2*p*, and Al 2*p* core levels in state-of-the-art conditions, and their thorough analysis shows the power of core photoemission spectroscopy, and its prominent utility, not only in surface physics, but more generally, in materials science.

However, clearly, the complete interpretation of photoemission spectra must go hand in hand with results from other complimentary methods, such as scanning tunneling microscopy, low energy electron diffraction, Auger electron spectroscopy, etc., and, overall, with first principles theoretical calculations of the involved atomic structures.

At present, a high-resolution core-level measurements can be easily performed at most synchrotron radiation facilities, where different photon energies can be used, in conjunction with optimized experimental geometries.

Now, such measurements concern more and more appealing studies of samples of great interest, such as the artificial 2D Xenos.

Hence, this spectroscopy, which is one of the best performing ones in the field of materials science, has reached its maturity both for fundamental researches and applied studies.

Further developments, typically for investigations in near ambient conditions, and in the time domain, which are already realized in practice, e.g., for catalytic studies in operando conditions, especially using novel 2D materials, undoubtedly promise a bright future to core photoemission.

Abstract

The generation of coherent light at frequencies that are integer multiples of those of ordinary laser sources may give access to useful and often unexplored spectral regions. Here, we briefly describe the basics of harmonic generation, which relies on the nonlinear interaction between matter and intense laser fields, to extend the range of the accessible electromagnetic spectrum toward shorter and shorter wavelengths.

Key points

- The generation of coherent light at frequencies that are multiples of those emitted by laser sources is briefly described.
- Basic elements are given of the processes involved in the nonlinear interaction between matter and laser light.
- The generation of the second harmonic and the phenomenon of phase-matching are described in some detail.
- High-order harmonics are introduced, with a simple physical picture and hints of their phase-matching properties.

Introduction

The ability to manipulate the frequency of laser light is essential for extending the range of possible spectroscopic investigations of matter in its different forms. Although the number of available laser lines is continuously growing, thanks to the introduction of new active materials operating in different spectral ranges, the extension toward the short-wavelength region of the electromagnetic spectrum would have been seriously limited without the advent of harmonic generation techniques, which rely on the nonlinear interaction between matter and intense laser light to generate new optical frequencies at integer multiples of the pump frequency.

With ordinary light sources, the electric fields associated to radiation are normally very small when compared to the typical local fields (of atomic, molecular, or crystal origin) inside materials. The electrons in atoms or the nuclei in molecules just explore the bottom of their potential wells (where the shape is approximately parabolic) under the influence of the external optical field, and their motion is harmonic with the same frequency of the forcing light (see Fig. 1).

The oscillating dipoles in the material are the sources of re-emitted radiation, whose spectral content is thus the same as the incident one. Many properties of light propagation in matter (such as refraction, reflection, dispersion, scattering, and birefringence) can be readily explained in this regime of linear optics. However, when the light field is so intense that it becomes a non-negligible fraction of the internal field, the linear approximation breaks down and the electrons or nuclei start exploring the anharmonic parts of their potential wells. In this regime, their motion is no longer harmonic and can be expanded in a Fourier series containing frequencies at integer multiples of the forcing frequency. Such new frequencies are also present in the radiation field emitted by the material and constitute the harmonics of the fundamental driving field.

[☆]*Change History:* September 2022. M Bellini updated the chapter. Compared to the first edition of this chapter, several new references have been added and slight changes have been made throughout the entire text. A new equation (24) has been included and a new paragraph appears at the end of the “Phase-matching in high-order harmonic generation” section. A conclusion section is also present at the end of the chapter.

Fig. 1 Potential energy curve illustrating the vibrational motion of nuclei in a molecule. The bottom of the curve can be well approximated by a parabolic potential and the motion is harmonic if only small-amplitude oscillations are induced by an external field.

In this article, the basics of harmonic generation are presented concisely, with an attempt to illustrate the fundamental physical mechanisms that are responsible for the processes at play (Shen, 2003; Boyd, 2019). A few examples are then given: from the simple case of second harmonic generation (SHG), dating back to the dawn of the laser era (Franken et al., 1961), to the production of high-order harmonics (McPherson et al., 1987; Ferray et al., 1988) in the extreme ultraviolet (XUV) and soft X-rays, which relies on the high peak intensities available to the current pulsed laser systems.

Nonlinear polarization and susceptibilities

When incident light is sufficiently off-resonance, its interaction with matter does not induce any change in the population of the energy eigenstates of the material system (i.e., no absorption takes place), but only provokes a perturbation of the motion of electric charges within the atoms or molecules. In this non-resonant process, the material is transparent to the incident radiation, but the change in charge distribution due to the oscillating light field results in an induced electric dipole moment which, in turn, acts as a new source to emit secondary electromagnetic waves: the induced polarization P is thus the source term that has to be introduced in Maxwell's equations, leading to the inhomogeneous wave equation

$$\nabla^2 E - \frac{1}{c^2} \frac{\partial^2}{\partial t^2} E = \mu_0 \frac{\partial^2}{\partial t^2} P, \quad (1)$$

for describing the subsequent field evolution. The general form for the component at frequency ω of the polarization vector P can be written as

$$P(\omega) = \sum_n P^{(n)}(\omega), \quad (2)$$

where the n th-order polarization has the following expression:

$$P^{(n)}(\omega) = \epsilon_0 \chi^{(n)}(\omega_1, \omega_2, \dots, \omega_n) E(\omega_1) E(\omega_2) \dots E(\omega_n) \quad (3)$$

and

$$\omega = \sum_{i=1}^n \omega_i \quad (4)$$

The quantities $\chi^{(n)}(\omega_1, \omega_2, \dots, \omega_n)$ are known as the nonlinear optical susceptibilities of order n of the medium, and they are $(n+1)$ th-order tensors relating an n -fold product of vector components E_j to a certain component of the n th-order polarization $P^{(n)}(\omega)$.

In the ordinary linear regime, the Fourier component at frequency ω of the polarization for a medium reduces to

$$P^{(1)}(\omega) = \epsilon_0 \chi^{(1)}(\omega) E(\omega) \quad (5)$$

with the obvious meaning that, in this first-order approximation, the polarization at a given frequency is linearly proportional to the incident field Fourier component at the same frequency: a monochromatic incident light can only induce a monochromatic secondary wave at the same frequency. For anisotropic media, $\chi^{(1)}(\omega)$ is a 3×3 -element second-order tensor, whereas it reduces to a complex function of the frequency for isotropic materials.

In the general case, the expression for $P^{(n)}(\omega)$ shows that, thanks to n th-order nonlinearities, it is possible to mix n incident waves at different frequencies to obtain an induced polarization, and thus some re-emitted radiation, at a different frequency: light at frequencies corresponding to sums and differences among the frequencies of the incoming beams can be produced this way. In the particular case where only one field at frequency ω enters the material, a susceptibility of order n can produce new radiation at $n\omega$, the n th harmonic of the incident field.

The ratio of two successive orders of polarization can be roughly estimated as

$$\left| \frac{P^{(n+1)}}{P^{(n)}} \right| = \frac{|\chi^{(n+1)}| |E|}{|\chi^{(n)}|} \approx \left| \frac{E}{E_m} \right| \quad (6)$$

where E is the amplitude of the applied optical field, and E_m is the characteristic value of the internal electric field in the material. If the main mechanism contributing to the nonlinear polarization is the distortion of the electronic cloud of an atomic or molecular system (as in the case of optical harmonic generation), then E_m is the average magnitude of the binding field experienced by the electrons ($\sim 10^{11}$ Vm $^{-1}$ for the hydrogen atom). For ordinary light sources, the ratio $|E/E_m|$ is normally so small that nonlinear polarization terms can be safely neglected. However, when laser light of high spectral intensity is used, the laser field may become a non-negligible fraction of the material field, and the second, third, and higher-order nonlinear terms, may start playing an important role, causing part of the incident light to be converted into the corresponding harmonic. From the above expression, one can also infer that the n th-order polarization, hence the field emitted at $n\omega$ is proportional to the n th power of the ratio between E and E_m (normally much smaller than 1), so that the probability of generating higher harmonics is expected to drop exponentially with the corresponding order in this perturbative approach.

From the fact that the susceptibility tensors must remain unchanged upon the symmetry operations allowed for the medium, one can simply conclude that for all isotropic media and centrosymmetric crystals, the even-order susceptibilities ($\chi^{(2)}, \chi^{(4)}, \dots, \chi^{(2n)}$) must be zero. Consequently, the generation of even-order harmonics is only possible in materials lacking inversion symmetry, whereas odd-order nonlinear effects can be exhibited by any media, although at different degrees of efficiency.

If the field amplitudes do not change much in a propagation length shorter than a wavelength (the so-called slowly varying amplitude approximation) and if nonlinearities are not too strong (so that the field amplitude at the pump frequency stays almost constant throughout the interaction), then one can find a simple expression for the wave equation of the plane-wave field and the induced nonlinear polarization P^{NL} oscillating at the new frequency ω'

$$\frac{\partial}{\partial z} E(z, \omega') = -\frac{i\mu_0\omega'^2}{2k'} P^{NL}(z, \omega') e^{i\Delta k z}, \quad (7)$$

where one assumes linearly polarized light (for reducing to a scalar equation) and collinear propagation along the z direction. The phase term $e^{i\Delta k z}$ accounts for the phase drift between the induced polarization and the generated electric field at ω' , and depends on the mismatch in their propagation vectors

$$\Delta k = k' - k_p \quad (8)$$

where $k_p = \sum_i \omega_i n(\omega_i)/c$ and $k' = \omega' n(\omega')/c$, with $n(\omega)$ the material refractive index at frequency ω .

In the case of harmonic generation of order q , this factor reduces to

$$\Delta k = k(q\omega) - qk(\omega) \quad (9)$$

Second harmonic generation

As a simple example, let us consider the case of second-order nonlinearity for the generation of radiation at twice the frequency of the incoming light (Franken et al., 1961). As seen above, symmetry considerations impose the process to take place in non-centrosymmetric crystals only. The polarization vector

$$P^{(2)}(2\omega) = \epsilon_0 \chi^{(2)}(\omega, \omega) E_1(\omega) E_1(\omega) \quad (10)$$

is the source term that has to be inserted in the wave equation and leads to the following expression for the variation of the field amplitude at the second harmonic $E_2(z)$:

$$\frac{\partial}{\partial z} E_2(z) = -\frac{i\omega d}{cn(2\omega)} E_1^2(z) e^{i\Delta k z} \quad (11)$$

where d corresponds to the component of the $\chi^{(2)}(\omega, \omega)$ tensor appropriate for the particular geometry of the laser-crystal interaction and

$$\Delta k = k(2\omega) - 2k(\omega) = \frac{4\pi}{\lambda} [n(2\omega) - n(\omega)] \quad (12)$$

is the phase mismatch factor, which takes into account the different phase velocities of the waves at ω and 2ω . If a negligible absorption and little production of the wave at 2ω are assumed, so that the pump field amplitude E_1 at frequency ω can be considered as almost constant, then the coupled wave equation can be integrated straightforwardly:

$$E_2(z) = -\frac{i\omega d}{cn(2\omega)} E_1^2(0) \int_0^L e^{i\Delta k z} dz \quad (13)$$

with the integration extending over the length L of the nonlinear medium. Assuming no initial second harmonic field, that is $E_2(0) = 0$, the integration yields:

$$E_2(L) = -\frac{\omega d}{cn(2\omega)} E_1^2(0) \frac{e^{i\Delta k L} - 1}{\Delta k} \quad (14)$$

and the output intensity of the second harmonic is thus proportional to

$$I_2(L) \propto d^2 I_1^2(0) L^2 \frac{\sin^2(\Delta k L/2)}{(\Delta k L/2)^2}. \quad (15)$$

Some simple observations can be made about this result: the amount of generated second harmonic light is proportional to the square of the intensity at the fundamental frequency; the efficiency is proportional to $|\chi^{(2)}|^2$ and to L^2 , but also contains a sinc^2 term involving L and Δk . The dependence of the emitted intensity at the harmonic frequency on the propagation distance and phase-mismatch is quite general and does not depend on the particular harmonic order considered. As seen above, passing to higher harmonic orders normally involves a rapidly decreasing value of the nonlinear coefficient d and a different power dependence on the incident intensity I_1 , but both the L^2 and the sinc^2 terms remain unchanged and play an important role in the harmonic generation of any order.

Only in the optimal conditions of phase-matching, with $\Delta k = 0$, does the efficiency actually scale quadratically with the medium length, and longer crystals are seen to produce more second harmonic. Note, however, that in these conditions the coupling between the fundamental wave and the second harmonic may become so strong that the depletion of E_1 while it propagates along z has to be taken into account, and some of the assumptions made above are no longer valid. In this so-called depleted-pump regime, a set of coupled equations for the pump field at ω and for the second harmonic field at 2ω has to be solved, and one finds that a complete transfer of the pump energy into the second harmonic field can be achieved.

Phase-matching

In the general case where $\Delta k \neq 0$, the intensity of the second harmonic field generated in a nonlinear crystal varies periodically along the z -axis with a period $2\pi/\Delta k$, and at a propagation distance of

$$L_C = \frac{\pi}{\Delta k} = \frac{\lambda}{4} \frac{1}{n(2\omega) - n(\omega)} \quad (16)$$

it reaches the first maximum, at a peak efficiency inversely proportional to Δk (see Fig. 2).

The physical explanation for this effect is related to the fact that, due to dispersion, the incident wave at frequency ω and the second harmonic wave at 2ω propagate in the medium with different phase velocities ($v_1 = c/n(\omega)$ for the fundamental and $v_2 = c/n(2\omega)$ for the second harmonic). Consequently, the two waves fall out of step with increasing distance in the crystal and the second harmonic waves generated at different places do no longer superpose in phase: after a distance L_C , destructive interference starts developing and it becomes complete, with the full disappearance of the wave at 2ω , at a distance of $2L_C$. L_C is the coherence length for SHG and defines the medium thickness for optimized conversion efficiency under the conditions of $\Delta k \neq 0$. Large Δk values lead to small SHG peak intensities and rapid variations with the distance, so that efficiency is severely limited for crystal lengths longer than L_C .

Fig. 2 Intensity of the second harmonic field vs. propagation distance in the nonlinear medium. A quadratic growth is obtained for perfect phase-matching conditions ($\Delta k = 0$), while oscillations of decreasing amplitude and period arise for increasing Δk .

The condition of $\Delta k = 0$ is referred to as the phase-matching condition and is achieved when $n(2\omega) = n(\omega)$. For ordinary waves in a medium with positive dispersion

$$n(2\omega) > n(\omega), \quad (17)$$

so one always gets $\Delta k \neq 0$, unless special conditions are met. In a birefringent material, different polarizations see different refractive indices. “Ordinary” and “extraordinary” refractive indices can be different by up to ~ 0.1 for SHG crystals, so one can satisfy the phase-matching condition by choosing the extraordinary polarization for one wave and the ordinary polarization for the other. For a negative uniaxial crystal ($n_o > n_e$), one can achieve phase-matching at a particular frequency ω if the relation $n_o(\omega) = n_e(2\omega)$ is satisfied (see Fig. 3).

Since the extraordinary index n_e depends on the propagation angle θ with respect to the optical axis of the crystal, one can phase-match the fundamental and second harmonic waves at different ω just by adjusting the angle of incidence on the crystal: the phase-matching condition in this case becomes $n_o(\omega) = n_e(2\omega, \theta_m)$, where θ_m is the so-called phase-matching angle. A geometric representation of this situation is obtained by plotting the refractive index curves for the ordinary and extraordinary waves at the fundamental and second harmonic frequencies (see Fig. 4). In such a representation, the refractive index n_e or n_o for each wave can be found at the crossing of the curves with the k -vector. In the negatively uniaxial crystal case, the point of intersection between the n_o circle at ω with the n_e ellipse at 2ω determines the phase-matching angle θ_m .

Note that in the quantum mechanical view of SHG, two photons of energy $\hbar\omega$ are absorbed during the excitation of the medium to a virtual state, and a single photon with an energy $2\hbar\omega$ is immediately re-emitted when the medium de-excites toward the ground state. In this framework, the phase-matching condition has the simple meaning of photon momentum conservation

Fig. 3 Phase-matching condition for a negative uniaxial crystal occurring for a particular frequency ω . In reality, the two curves for n_o and n_e represent the maximum and the minimum attainable index of refraction in the crystal, and the whole range in between the two curves can be covered by the extraordinary index n_e by changing the angle between the propagation vector and the optical axis of the medium. So, by choosing the appropriate angle, phase-matching can be obtained for different frequencies.

Fig. 4 Geometric construction for the determination of the phase-matching angle θ_m in a negative uniaxial crystal.

$$k_1 + k_1 = k_2 \quad (18)$$

between the initial and the final states of the system.

Although it was discussed in the particular case of SHG, phase-matching is a much more general issue and is always present in all nonlinear optical phenomena where waves at new frequencies are to be generated with the highest possible efficiency. In the most general case of n waves with wave vectors k_i participating in the nonlinear process, one has to make sure that the total photon momentum is conserved in the interaction by satisfying the condition

$$\sum_{i=1}^n k_i = 0 \quad (19)$$

Quasi phase-matching

As seen above, when perfect phase-matching is not achieved, the fundamental and second harmonic fields slip out of phase after a propagation distance L_C and the conversion efficiency oscillates without growing monotonically with L^2 as it should do in the case of $\Delta k = 0$ (Fig. 5). A clever solution to improve the conversion efficiency would consist in properly adjusting the phase of the nonlinear polarization after each coherence length (Armstrong et al., 1962). Ideally, one should flip the sign of the nonlinear coefficient (and thus the sign of the polarization) with a periodicity L_C . Under these circumstances, the nonlinear intensity would keep growing monotonically, although less rapidly than in the case of perfect phase-matching, and long interaction lengths could be used to boost the conversion efficiency.

Such a quasi-phase-matching (QPM) condition can be achieved in so-called periodically-poled materials (Hum and Fejer, 2007), generally ferroelectric crystals (LiNbO₃ is among the most frequently used) where regions of periodically reversed polarization domains are permanently written by applying strong spatially-shaped static electric fields (Fig. 6).

If technological limitations do not allow one to realize the right spacing between the inverted domains (it is currently difficult to obtain poling periods much smaller than $\sim 5 \mu\text{m}$), a higher-order QPM can be obtained by flipping the nonlinear coefficients every 3 (third-order QPM), 5 (fifth-order QPM), or any odd number of coherence lengths. However, the conversion efficiencies in these cases are clearly lower than those achieved with first-order QPM.

Fig. 5 Intensity of the second harmonic field vs. propagation distance in different phase-matching conditions. For QPM, the sign of the nonlinear coefficient of the crystal is reversed every coherence length L_C in order to get a monotonous increase of the second harmonic intensity. The perfect phase-matched condition (PM) and the mismatched situation (no PM) are also shown.

Fig. 6 Schematic of SHG in a periodically poled crystal with several layers of alternately-oriented domains.

High-order harmonic generation

Current amplified pulsed laser systems can routinely reach peak intensities of $\sim 10^{15}$ – 10^{20} W cm $^{-2}$ and, in these situations, the perturbative approach used above to model the nonlinear response of materials to radiation is no longer adequate. As a matter of fact, at a peak intensity of 3.5×10^{16} W cm $^{-2}$, the amplitude of the oscillating laser electric field corresponds to the field that binds an electron to the proton in the ground state of a hydrogen atom. The assumption that successive terms of the expansion of medium polarization in powers of the incident field get progressively smaller with the order clearly cannot hold in these conditions.

The most impressive consequence of the breakdown of the perturbative approach is the deviation from the expected exponential decay of the intensity of successive harmonic orders (see Fig. 7). The appearance of a so-called plateau, a region of the spectrum where several harmonics are generated with almost constant efficiency, is the characteristic feature of high-order harmonic generation (HHG) in gases (Ferry et al., 1988; McPherson et al., 1987).

Here, short and intense laser pulses are typically focused in a pulsed gas jet (see Fig. 8) to produce coherent radiation in the extreme ultraviolet (XUV) and soft X-rays, a wavelength range (1–100 nm) where the lack of coherent sources has greatly limited the possibility of spectroscopic investigation, so far.

As a consequence of the isotropy of the gaseous medium, only odd-order harmonics are generated, and one finds that the region of efficient production of high harmonics is limited by a so-called cutoff. The most energetic photons generated in the process possess a cutoff energy E_{cutoff} , which is found to follow the simple law (Krause et al., 1992):

$$E_{\text{cutoff}} \approx I_p + 3.2U_p \quad (20)$$

where I_p is the ionization potential of the atoms in the gas jet, and U_p is the ponderomotive energy, which corresponds to the mean kinetic energy acquired by an electron in one cycle of oscillation in the laser field:

$$U_p = \frac{e^2 E^2}{4m\omega^2} \quad (21)$$

with e and m the electron charge and mass, respectively, E the amplitude of the laser field, and ω its frequency. It is evident that high laser intensities and high ionization potentials are required in order to reach very short wavelengths. Indeed, rare gas atoms and

Fig. 7 Schematic view of the typical behavior of high-order harmonic spectra. Only odd-order harmonic photons are generated, with successive harmonics separated by twice the energy of the pump laser photons. The first harmonics follow the predictions of the perturbative approach, with intensities exponentially decreasing with the order. Then, a plateau is formed and extends up to E_{cutoff} .

Fig. 8 Typical scheme for HHG in a gas jet.

ultrashort pulses of very high peak intensity are normally used to generate high harmonics. A further advantage of using hard-to-ionize gases and short pulses is given by the requirement that neutral atoms survive long enough to experience the full peak pulse intensity instead of being completely ionized at the leading edge of the pulse itself. If $W(I)$ is the atomic ionization rate and τ_p the pulse duration, then the maximum effective intensity useful to produce harmonic photons is the so-called saturation intensity I_s , approximately given by the relation $W(I_s)\tau_p = 1$. $W(I)$ being a monotonously increasing function of I , higher saturation intensities can be reached with shorter laser pulses and, of course, with light noble gases having higher ionization potentials.

The three-step model

The standard picture of the HHG process can be easily visualized from a semiclassical perspective in a single-atom approach (Corkum, 1993): in every half optical cycle of the laser pulse, electrons undergo tunnel ionization through the potential barrier formed by the atomic potential and by the electric field potential of the laser itself; after being accelerated in the ionization continuum by the field, they may come back to the ion core and recombine to emit harmonic photons that release the accumulated kinetic and ionization energy (see Fig. 9).

Some of the most relevant features of harmonic radiation can be simply obtained by using this single-atom picture and solving the classical equations of motion for an electron, freed with zero velocity at different moments in an oscillating electric field. Depending on the phase of the field at the moment of ionization, the electron can either escape from the parent ion or oscillate in the field and come back to the original position after a fraction of the optical period T . Only electrons ionized within $T/4$ after each field maximum contribute to the harmonic emission by recombining with the ion and converting their kinetic and potential energy into photons (see Fig. 10).

The experimentally found cutoff law can be simply obtained by noting that the maximum return kinetic energy (brought back by electrons that escape slightly after each field maximum every half optical cycle) corresponds to $\sim 3.17U_p$ (see Fig. 11). For the generation of harmonics with photon energies below the cutoff limit, there are always two different trajectories (corresponding to two different release times within each half cycle) that the electron can follow in the continuum, such that it returns to the ion core with the correct energy. These two trajectories, although giving rise to photons with the same energy, may correspond to quite different permanence times of the electrons under the influence of the laser field, and some of the spatial and temporal characteristics (phase-matching relations, defocusing, and frequency modulation) of the emitted harmonic radiation will thus be strongly affected (Gaarde et al., 1999; Bellini et al., 1998).

Harmonic emission during a single pump pulse is thus seen to be composed of a train of XUV photon bunches, essentially released twice every optical cycle of the laser field. This temporal structure translates into the characteristic spectral structure of high-order harmonics, with peaks corresponding to the odd orders, separated by twice the laser frequency.

The semiclassical model also offers a simple explanation for other experimentally observed characteristics of harmonic radiation. A linear polarization of the laser is needed to make sure that the electron oscillating in the field may “hit” the ion and recombine with it when it comes back after the oscillation in the continuum; experiments have shown that just a small degree of ellipticity is sufficient to

Fig. 9 The three-step model for HHG. Electrons are first tunnel-ionized by the intense laser field, then they are accelerated during an optical cycle and finally recombine with the parent ion, thus releasing the accumulated kinetic energy in the form of harmonic photons.

Fig. 10 Schematic representation of the main electron trajectories involved in the HHG process (only the first half optical cycle is considered for simplicity, but things repeat with a $T/2$ periodicity). Electrons that are ionized when the absolute value of laser field amplitude is growing, just escape from the ion and do not contribute to the process, while electrons released after the peak can come back to the core position and recombine to emit harmonic photons. Electrons ionized in *A* return with the maximum kinetic energy (related to the slope of the trajectory as it crosses the horizontal axis) and generate the most energetic photons in the cutoff region. Electrons released in *B* and *C* follow different trajectories in the continuum but return with the same kinetic energy (same slope at axis crossing), thus both contribute to the generation of the same harmonic.

Fig. 11 Upper curve: plot of the return kinetic energy for electrons ionized at different times during the optical cycle. The origin of the time axis is fixed at the peak of the field amplitude for each half optical cycle. A single trajectory, corresponding to electrons emitted in *A*, is responsible for the emission of a cutoff harmonic, while two distinct trajectories (originating in *B* and *C*) contribute to the generation of a harmonic in the plateau. Lower curve: time (here indicated as the “return time”) that the electrons spend oscillating in the continuum before re-combining with the ion. Plateau harmonics mainly come from two classes of electrons with distinct return times.

completely inhibit the generation of harmonics. It is also clear that, although the expressions for E_{cutoff} and U_p seem to favor long-wavelength pump pulses for the generation of high harmonics, actually, the longer time that it takes for the electron to return to the ion (proportional to the pump laser wavelength) implies a significant spreading of the electron wave packet during its oscillation and a final lower overlap with the ion wave function, which in turns causes the probability of recombination to decrease.

Phase-matching in high-order harmonic generation

The three-step model is an excellent way to understand the single-atom response of the gas medium to the intense electric fields of the laser. However, when the global response of the system is considered, propagation effects have to be included (Balcou et al., 1999). Phase-matching is again an essential condition for the efficient generation of high-order harmonics to take place. In this case, the fundamental and the harmonic field can fall out of phase for several reasons: besides the usual dispersion in the neutral gaseous medium (which may, however, contain both linear and nonlinear contributions, due to the high intensities involved), the geometrical

dephasing due to the focusing of the Gaussian laser beam can introduce an additional phase shift, as well as the dispersion introduced by the generated free electrons, and the so-called dipole-phase variation. In order to achieve a sufficiently high conversion efficiency, the phase shift between the polarization of the q th harmonic and the generated harmonic field has to be kept as constant as possible over all the interaction region.

As for the dispersion by the neutral medium, the corresponding phase shift on a propagation distance z has the usual form

$$\Delta\phi_{ND} = \frac{2\pi qz}{\lambda} [n(q\omega) - n(\omega)] \quad (22)$$

and the refraction indices at the two frequencies clearly depend both on the gas density in the jet and on the fraction of neutral atoms left after the partial ionization by the laser pulse. The dispersion caused by free electrons produced in the interaction becomes important as soon as the intensity approaches the saturation intensity I_s and has to be accounted for by introducing the index of refraction

$$n_{el}(\omega) = \sqrt{1 - \frac{\omega_p^2}{\omega^2}} \quad (23)$$

where ω_p is the so-called plasma frequency, which is related to the local free-electron density n_e as

$$\omega_p = \sqrt{\frac{n_e e^2}{m \epsilon_0}}. \quad (24)$$

The corresponding phase shift is thus approximately given by

$$\Delta\phi_{el} \approx \frac{z\omega_p^2}{2c q \omega} (q^2 - 1) \quad (25)$$

The on-axis phase shift across the focus of a Gaussian beam is $\phi(z) = \tan^{-1}(2z/b)$, where b is the laser confocal parameter. The phase shift due to this geometrical effect is then

$$\Delta\phi_G = (1 - q) \tan^{-1}(2z/b) \quad (26)$$

Finally, one finds that the laser-induced polarization has an intrinsic intensity-dependent phase that arises from the phase of the wave function of the electrons generating a particular harmonic. The two main electronic trajectories contributing to the dipole moment of a given plateau harmonic induce a phase that is proportional to the intensity of the driving laser field, and to the amount of time the electron has spent in the continuum (Gaarde et al., 1999; Corsi et al., 2006). For each trajectory (labeled by j), this leads to an intensity-dependent variation of the phase

$$\Delta\phi_{D,j} = -\alpha_j I(z, t) \quad (27)$$

summing up to a total dipole phase:

$$\Delta\phi_D = \sum_j \Delta\phi_{D,j}. \quad (28)$$

All these contributions to the phase slip between the induced polarization and the generated harmonic field combine to give a total phase mismatch

$$\Delta\phi = \Delta\phi_{ND} + \Delta\phi_{el} + \Delta\phi_G + \Delta\phi_D \quad (29)$$

that should not vary too much across the medium length. Unfortunately, most of the above terms have a complicated dependence on the detailed spatio-temporal dynamics of the atom—laser interaction, and the task of keeping $\Delta\phi$ fixed is normally a very difficult one, unless special simplifications can be made in order to neglect one or more of the contributions to the total phase-mismatch. Using collimated laser beams or propagation in hollow fibers can null the geometrical phase shift, whereas keeping a low ionization level can eliminate the free-electron contribution to dispersion. When the experimental conditions are achieved so that positive and negative terms partially cancel out in the expression for $\Delta\phi$, a strong enhancement in the conversion efficiency of a particular high-order harmonic can be obtained.

Recently, it has been shown that quasi phase-matching can be achieved also in the generation of high-order harmonics. A periodic modulation in the diameter of the hollow fibers (Gibson et al., 2003; Paul et al., 2003) or in the gas density (Pirri et al., 2008) in the interaction region where harmonics are produced have proved effective in strongly and selectively enhancing the yield of particular harmonic orders.

Conclusion

In this chapter, I concisely introduced some of the main concepts illustrating the conversion of the electromagnetic field frequency by means of harmonic generation. I briefly outlined the underlying physical mechanisms governing this phenomenon and gave

some specific examples for the generation of the second harmonic and for the other extreme condition of high-order harmonics. Harmonic generation techniques, relying on the nonlinear response of matter (from natural crystals to artificial photonic structures and gas jets) to intense light, date back to the early days of the laser era and have since revolutionized the way we produce coherent light for applications in spectral regions that currently extend from the microwaves to the X-rays.

Abstract

The basic features of this family of techniques are discussed, beginning with its historical development. Angle-resolved (band mapping) and angle-integrated techniques are analyzed as well as a series of experimental approaches requiring powerful photon sources such as undulators at synchrotrons or free electron lasers. Such techniques include photon polarization spectroscopy, experiments with variable photon energy, photoemission resonances and techniques affected by low signal levels such as time-resolved photoemission, two-photon photoemission, spectromicroscopy and spin-polarized photoemission. Finally, high-resolution photoemission studies of superconductors and of other highly correlated systems are briefly discussed.

Key points

- The photoelectric effect
- Information content of photoemission spectroscopy
- Role of synchrotron sources
- High brightness: special techniques
- Correlated systems

Introduction

The photoelectric effect (Hertz, 1887) is the basis of some of the most powerful techniques for analyzing the electronic structure of condensed-matter systems. These are the approaches collectively called “photoemission spectroscopy” (Cardona and Ley, 1978–1979; Hufner, 2003, 2010; Lynch and Olson, 1999; Prince, 2003; Rabalais, 1977; Van Howe and Schattke, 2003; Margaritondo, 2023; De Padova, 2023; Margaritondo, 2005).

Even before the development of such techniques, the photoelectric effect had a fundamental (and often not correctly understood) impact on the development of modern science. The main milestones after Hertz’s result were the discovery of the electron (Thompson’s, 1897), Einstein’s hypothesis on the photon (Einstein, 1905), and Millikan’s (reluctant) experimental validation of Einstein’s hypothesis (Millikan, 1918).

Einstein derived the photon hypothesis with a purely thermodynamic argument and used it to predict the frequency threshold in the photoelectric effect, which was not experimentally verified until the late 1910s. The photoelectric effect contributed in this way to the experimental foundations of quantum physics. This was of course a very significant element in the development of modern physics.

The next scientific impact of the photoelectric effect was its practical use in spectroscopy, which came almost 40 years later. The reason for this long delay is the confinement of the photoelectric effect to the region near the surface of the photoelectron-emitting solid. In order to become a photoelectron, the electron must absorb a photon and increase its energy above the photoelectric threshold, i.e., the energy barrier that keeps it in the solid. Since the threshold is of the order of several eV’s, the photon must be in the x-ray or ultraviolet spectral range. Photons of these energies can penetrate quite deep in the solid before being absorbed.

However, the electrons excited by absorbing them can travel only over a very short distance before losing energy. As a consequence, photoelectrons originate only from a very thin slab near the surface of the sample. And they carry information on the electronic structure of that slab, which includes a very few atomic planes.

[☆]Change History: November 2022. G Margaritondo updated the chapter. All sections and figures were updated.

If the surface is contaminated, the information reflects the properties of the solids mixed with those of the contaminant. To avoid this problem, a clean surface can be obtained by several different methods such as cleaving, scraping, and in situ growth. However, the surface does not stay clean for a reasonable time unless it is kept under ultrahigh vacuum (pressure $< 10^{-9}$ Pa). This kind of vacuum could not be routinely achieved before the 1960s: this explains the long delay in the practical use of the photoelectric effect for photoemission spectroscopy.

After solving the contamination problem, photoemission spectroscopy initiated a strong and steady expansion. This growth was accelerated in the late 1960s by the advent of synchrotron radiation sources (Hwu and Margaritondo, 2021; Margaritondo, 1988, 2003). With their help, photoemission became a leading tool for probing the electronic structure of solids and of condensed systems in general.

The information content

Solid-state photoemission explores the electronic states inside the specimen. An electron quantum state $|k\rangle$ in a crystalline solid is defined, according to the Bloch theorem, by the “crystal momentum” k -vector k . This vector cannot be directly measured if the electron is inside the solid: only indirect information can be obtained, for example from optical experiments.

After an electron becomes a free photoelectron in vacuum, its state $|k_o\rangle$ can be measured. In fact, the magnitude of the k -vector k_o is given by the free-photoelectron (kinetic) energy K : $|k_o| = (2m_o K)^{1/2} \pi / h$ (where m_o is the electron mass). And the direction of k_o is that of the free photoelectron motion.

From the measured properties of $|k_o\rangle$ one can derive those of the initial state $|k\rangle$ inside the solid. The main steps are the following. One must measure K with a suitable energy analyzer. And one must also determine the direction of k_o by using an analyzer with angular resolution. Finally, one must connect the measured information on $|k_o\rangle$ to the properties of $|k\rangle$: this is not an easy task.

In fact, the connection is determined by the photoemission process, which is a complex combination of different phenomena interfering with each other. Historically, the task was conceptually simplified (Puff, 1964; Berglund and Spicer, 1964) by considering the overall process as the combination of different *independent* steps: excitation of the electron from the state $|k\rangle$ upon absorption of a photon, transfer of the excited electron to the surface and then emission in vacuum.

This simplified vision created the conceptual background of modern photoemission spectroscopy, whose strategy is schematically illustrated by Fig. 1: photons of a specific energy $h\nu$ are used to bombard the ultraclean surface of the solid under investigation and to transform electrons in the quantum state $|k\rangle$ into photoelectrons. The photoelectrons are collected and their flux per unit time is measured as a function of the kinetic energy K . This approach can be used to study both core electrons and valence electrons: our present discussion, however, is limited to the latter case.

Fig. 1 (A) The photoelectric effect, the foundation of photoemission spectroscopy. (B) The kinetic energy K of a photoelectron is determined according to Eq. (1) by the photon energy $h\nu$, by the work function ϕ and by the initial energy of the electron in the solid or binding energy E_B ; VL is the vacuum level; and E_F is the Fermi level. (C) In angle-resolved photoemission, photoelectrons are collected selecting their direction of emission. This determines not only the energy of the photoelectron but all the properties of its k -vector k_o . Reproduced from Margaritondo G (2005) Encyclopedia of Condensed Matter Physics, 1st edn. Amsterdam: Elsevier, 279–286.

In the early stage of the history of photoemission spectroscopy, the experiments collected photoelectrons without selecting their direction. This is no longer true today, when the technique of preference is “angle-resolved photoelectron spectroscopy” or ARPES.

Fig. 1B illustrates the essential features of the photoelectron energy analysis in the case of a metallic solid, with electrons distributed in energy up to the “Fermi level” E_F . The zero of the photoelectron kinetic energy is called the “vacuum level” (VL): this is the minimum energy required for an electron to leave the solid. The distance between VL and E_F is the “work function,” Φ . The kinetic energy K of a photoelectron is given by Einstein’s equation (Einstein, 1905):

$$K = h\nu - E_B - \Phi, \quad (1)$$

where E_B , the energy distance between the electron in the solid and E_F , is called the “binding energy.”

Eq. (1) shows that by measuring K and knowing Φ and $h\nu$ one can extract the initial energy of the electron, E_B . This is the first information about the initial state $|k\rangle$ of the electron in the solid.

Consider now angle-resolved photoemission (Fig. 1C), which measures the photoelectron direction completing the information on the final state $|k_o\rangle$. How can this be connected to the initial state $|k\rangle$? Eq. (1) provides the answer for the energy. But the answer for the direction is not immediate.

In particular, the passage from the solid to vacuum changes the k -vector component perpendicular to the surface. One must thus estimate this change. Several clever schemes were developed to solve this problem.

The situation is simplified when the system under investigation has a two-dimensional (or one-dimensional) character – for example, it is a layered solid or a crystal surface. In that case, only the parallel component of k matters, which (in most cases) is equal to the parallel component of k_o .

Angle-resolved photoemission experiments can thus experimentally determine both the electron energy E_B and its momentum vector k . Thus, they probe the 3-dimensional $E_B(k)$ function in different directions. For crystalline solids, this function is the so-called “band structure.”

Using angle-resolved photoemission to derive $E_B(k)$ is known as “band mapping.” Fig. 2 shows an example of band mapping, including the raw photoemission data and a portion of the corresponding derived $E_B(k)$ function.

As mentioned, in the early and most elementary version of photoelectron spectroscopy photoelectrons were detected without selecting their direction, i.e., using an electron energy analyzer with a large detection area that mixed together a broad range of directions. This was practically unavoidable when the signal level was too low for angle-resolved photoemission. Furthermore, angular scrambling automatically occurs for polycrystalline samples and, to some extent, for sample surfaces cleaned by scraping.

In all these cases, plots of the photoelectron distribution in energy (energy distribution curves or EDC’s) reproduce the electron “density of states,” in the solid. This information is valuable to test the theoretical results on the electronic structure – but is of course reduced with respect to angle-resolved photoemission.

Photoemission with synchrotron sources

So far, we only mentioned photoemission experiments performed as a function of the electron energy and direction. However, several other parameters can be controlled during a valence-electron photoemission experiment, enhancing the extracted information. These parameters notably include the energy, polarization and direction of incidence of the photon, as well as the photoelectron spin polarization.

Fig. 2 An example of the band-mapping technique (Zwick et al., 1998): Angle-resolved photoemission spectra for the material TTF-TCNQ. Note the dispersing peak in the low-binding energy region. Reproduced with permission from Zwick F, Jérôme D, Margaritondo G, Onellion M, Voit J and Griani M (1998) *Physical Review Letters* 81: 2974–2977, © 1998 APS.

Controlling the above parameters requires a suitably high signal level, i.e., a high flux of photoelectrons. In turn, this corresponds to a high intensity of the photon beam. In modern photoemission, this is achieved using as photon sources synchrotrons or free electron lasers (Hwu and Margaritondo, 2021), which offer superior flux and brightness. This is particularly important in techniques with chronically low signal levels such as spin-polarized photoemission.

Furthermore, synchrotron sources emit polarized photons. And they also offer the possibility to “tune” the photon energy within the x-ray and ultraviolet range required for photoemission.

The photon polarization can be directly exploited to probe the symmetry of the valence electronic states. The theoretical background of this approach is the following. We have seen that the emission of photoelectrons requires excitation by photon absorption. For a given initial electronic state, the excitation may or may not be allowed depending on the symmetry of the initial and final electron state as well as on the photon polarization (and direction). Therefore, the symmetry of the initial electronic state can be identified by carefully analyzing the photon polarization dependence of the photoemission spectra.

In essence, the analysis is similar to that of (ultraviolet or x-ray) optical absorption spectra. Since the excited electron is in a high-energy, free-electron-like state, the photon polarization effects are mostly determined by the symmetry of the initial state. And can indeed be used to identify it. Fig. 3 shows an early example of this simple and powerful approach.

Interesting photoemission experiments are also performed using the circular polarization of special synchrotron sources such as the “helical wigglers.” These experiments provide very valuable information, notably about magnetic systems.

Using the conceptual separation of the photoemission process in independent steps, one can also understand its dependence on the photon energy. The photoelectron emission is determined by the excitation probability for the first step, which in turn is determined by the corresponding Fermi’s optical “matrix element.” The matrix element depends both on the initial state and on the final state of the excitation.

When analyzing a given initial state with energy E_B , different photon energies correspond to different final states and, therefore, to different matrix element values. This influences the intensity of the spectral features. Such “matrix element effects” can significantly modify the photoemission spectra, producing in some cases spurious and potentially misleading features.

As a general rule, when the electrons are optically excited to high energies by high-energy photons, their states become free-electron-like and the matrix element effects are negligible. However, most valence-electron photoemission experiments are conducted with low photon energies (15–30 eV) and are not immune from such effects. Indeed, the use of low $h\nu$ ’s is preferable since by lowering $h\nu$ the transition probability tends to increase leading to higher signal levels. Furthermore, for a constant resolving power $h\nu/\Delta h\nu$ of the photon source, the absolute photon energy resolution $\Delta h\nu$ becomes better for smaller $h\nu$ ’s.

As a consequence, matrix element effects must be considered in the data analysis. To avoid mistakes, one must take photoemission spectra at several different photon energies and compare the results.

This requires a photon source with tunable photon energy, that is, a synchrotron source. Specifically, a synchrotron source based on a “bending magnet” emits a broad band of $h\nu$ ’s, from which the desired photon energies can be filtered with a monochromator.

Fig. 3 Photon polarization effects in the (angle-integrated) photoemission spectra of a cleaved Si(111) surface covered by chemisorbed chlorine. Note the strong decrease of the feature at $E_B = 6\text{--}7$ eV as the photon polarization changes from p to s. By analyzing the data in terms of the optical excitation induced by photon absorption, the symmetry of the initial electronic state corresponding to this feature was identified as σ_{pz} . (Schluter et al., 1976). Reproduced with permission from Schluter M, Rowe JE, Margaritondo G, Ho KM, and Cohen ML (1976) *Physical Review Letters* 37: 1632–1635, © 1976 APS.

An “undulator” source provides a narrow band of photon energies centered at a tunable value; however, further monochromatization is required for photoemission experiments.

In addition to the identification of matrix element effects, the control of the photon energy provided by synchrotron sources opens up many other experimental opportunities. Consider, for example, the surface sensitivity of photoemission experiments. We have mentioned that photoelectrons are only emitted from a thin slab near the sample surface. The thickness of this slab, called “escape depth,” changes with the photoelectron kinetic energy K (see Fig. 4), which in turn depends (Eq. 1) on the photon energy.

Therefore, by changing the photon energy and therefore K one can increase or decrease the surface sensitivity. Roughly speaking, experiments with K -values higher than 100 eV or lower than 50 eV tend to be less surface-sensitive than experiments with K -values ranging between 50 and 100 eV. This is useful to distinguish surface effects from bulk effects.

The photon energy tunability is also helpful in identifying the symmetry of the initial electronic states in the solid. Matrix element effects can, in fact, be exploited for “labeling” such states. This is a rather complex task. But it can be strongly simplified by the presence of “photoemission resonances.”

Such resonances are very rapid and strong variations of the intensity of certain photoemission features when the photon energy is changed. A resonance typically occurs for photon energies near a core-level absorption threshold of a given element and affects valence states related to the same element. Therefore, a resonating photoemission feature can be immediately attributed to the corresponding element. Fig. 5 shows an example of this powerful approach.

Fig. 4 The escape depth of photoelectrons plotted as a function of the kinetic energy is slightly different from material to material. For all samples, however, the depth falls in the shaded area and exhibit a minimum (corresponding to the maximum surface sensitivity of photoemission experiments) at $K = 50$ – 100 eV. Reproduced from Margaritondo G (2005) *Encyclopedia of Condensed Matter Physics*, 1st edn. Amsterdam: Elsevier, 279–286.

Fig. 5 Photoemission spectra for the YBCO high-temperature superconductor reveal a resonating feature at $E_B = 14$ – 18 eV when the photon energy varies near the Ba5p absorption edge. This photoemission resonance immediately identifies the feature as due to Ba-related electronic states (Onellion et al., 1987). Reproduced with permission from Onellion M, Chang Y, Niles DW, Joynt R, Margaritondo G, Stoffel G, and Tarascon JM (1987) *Physical Review B* 36: 819–821, © 1987 APS.

The tunability of synchrotron sources is also exploited in specialized photoemission techniques in which the photon energy is continuously changed rather than kept constant. One should note, in particular, G. J. Lapeyre's constant initial state (CIS) technique, in which both $h\nu$ and the kinetic energy K of the photoelectron are scanned while keeping constant their difference. According to Eq. (1), this implies that $E_B = h\nu - K - \Phi$ stays constant. Therefore, the detected photoemission intensity reflects the properties of the final states of the excitation rather than those of the initial state. This technique can thus be used to explore final (empty) valence states.

Techniques requiring high-brightness synchrotron sources

We already mentioned the importance of the very high flux and brightness of synchrotron sources for techniques with intrinsically low signal levels. Consider, for example, the difficulties in achieving high lateral resolution in a photoemission experiment. In general, the experiments are performed without lateral resolution: the detector collects photoelectrons from a rather large sample area in order to reach a reasonable signal level. This implies that the investigated electronic structure is averaged over the same area. In the case of inhomogeneous samples, the averaging could lead to misleading results.

High lateral resolution is therefore desirable, transforming "photoemission spectroscopy" into "photoemission spectromicroscopy." The corresponding decrease in signal level, however, must be compensated by using a high-brightness synchrotron source, such as an undulator.

The same requirement is present for time-resolved photoemission. In a standard photoemission experiment, the signal is accumulated over a certain period of time to reach an acceptable signal-to-noise ratio. This is of the order of several seconds per data point and of several minutes per spectrum, impeding studies of time-dependent phenomena over a shorter time scale.

The great interest of such phenomena triggered a substantial effort – based again on high-brightness sources – to decrease the data-taking time. The most spectacular results are now achieved with short laser pulses. The required photon energies for photoemission are obtained by multiplying the photon energy of low- $h\nu$ ultrashort laser pulses with nonlinear optical devices. In recent years, however, high- $h\nu$ pulses were directly delivered by ultraviolet and x-ray free electron lasers.

Ultrashort photon pulses can be used to directly excite photoelectrons. Another possible approach, called "two-photon photoemission," consists of using a low- $h\nu$ laser pulse to bring valence electrons into an excited state and then to use a high- $h\nu$ pulse to extract them as photoelectrons, as shown in Fig. 6. This approach is used to study the dynamic properties of excited states. Techniques in this class can reach the picosecond or sub-picosecond time range. Their impact is currently enhanced by the use of free electron lasers.

Spin-polarized photoemission is another valence-electron technique that is chronically affected by low signal levels. Experiments discriminating the spin polarization of the photoelectrons require special detectors with typically limited effectiveness. These difficulties notwithstanding, spin-polarized photoemission has evolved to become one of the most important subfields in this domain, providing extremely valuable information, for example on the valence states of magnetic systems.

Valence photoemission of correlated systems

The discovery of high-temperature superconductors and many subsequent experimental and theoretical results increased the need of experimental probes to study electron correlation. Photoemission was able to play a crucial role, primarily because of a substantial increase in its energy resolution.

Fig. 6 Schematic illustration of a two-step photoemission process involving a low-energy laser photon ($h\nu_1$) that brings a valence electron into an excited state and a synchrotron (or free electron laser) high-energy photon ($h\nu_2$) to extract it as a photoelectron. Reproduced from Margaritondo G (2005) Encyclopedia of Condensed Matter Physics, 1st edn. Amsterdam: Elsevier, 279–286.

Roughly speaking, phenomena related to the formation of chemical bonds affect valence electrons within 10–20 eV of the Fermi level. Except in specialized cases, their study with photoemission techniques does not require an energy resolution better than ≈ 100 meV.

On the contrary, correlation phenomena occur on a smaller energy scale. A typical example is provided by the superconducting gap, which even for high-temperature superconductors does not typically exceed a few tens of meV. The study of such phenomena requires energy resolutions beyond 50 meV – and in some cases of 1–2 meV or better.

Experimental systems capable of achieving these performances were developed and used to explore superconductors as well as other correlated systems. Fig. 7A shows a typical result of these experiments: the opening of the superconducting gap during the phase transition of the high-temperature superconductor bismuth strontium copper oxide (BCSCO).

Note the high-energy edge in the normal-state spectrum, corresponding to the Fermi level. In the superconducting state, the edge recedes revealing the opening of the superconducting gap. Furthermore, the spectrum exhibits other interesting features – such as the strong quasiparticle peak immediately below the gap and the subsequent “dip” – that have generated much interest.

Fig. 7B shows another example of the valuable information that can be extracted with high-resolution photoemission. Superconducting-state spectra taken along different directions reveal different values of the gap, ruling out theoretical models that predict isotropy.

Correlated systems can sometimes exhibit rather “exotic” phenomena departing from the standard frameworks of solid-state physics. This framework is Landau’s “Fermi liquid,” in which the free electrons of a Fermi gas are replaced by dressed quasiparticles with electron-like properties. The soundness of this theoretical foundation is evident in most photoemission results: for example, the spectrum of metallic samples (Fig. 8; Perfetti, 2002) typically exhibits a Fermi-level cutoff reflecting the edge of the Fermi–Dirac distribution.

However, high-resolution photoemission experiments on low-dimensional systems sometime reveal phenomena departing from the Fermi-liquid framework. Fig. 8, for example, also includes photoemission spectra of one-dimensional materials that, although metallic, do not exhibit a Fermi-edge cutoff.

Experiments in this domain explore alternate theoretical frameworks that could replace the Fermi liquid in highly correlated low-dimensional systems, such as the “Luttinger liquid.” Such frameworks lead to exotic notions, such as the replacement of the holes of the Fermi liquids with spin-carrying “spinons” and charge-carrying “holons.”

Correlation affects not only the initial state but the entire photoemission process. The simplest approach to analyze photoemission results treats the electrons (or the Fermi-liquid quasiparticles) as a gas of independent particles. The emitted photoelectrons are thus also treated as isolated entities.

This is not really correct, in particular for correlated systems: the photoemission process should be rigorously treated as the transition from a many-body correlated state to another many-body state plus a free electron. This, of course, complicates the theoretical treatment, but also enhances the quality and quantity of information that can be extracted from photoelectrons.

Fig. 7 (A) High-resolution photoemission spectra taken on the high-temperature superconductor BCSCO at temperatures corresponding to the normal and superconducting state reveal the opening of the superconducting gap (shaded area) (Hwu et al., 1991). (B) Superconducting-state spectra taken for the same compound along different crystallographic directions reveal the anisotropy of the superconducting gap (Kelley et al., 1994). (B) Reproduced with permission from Kelley RJ, Ma J, Quitmann C, Margaritondo G, and Onellion M (1994) *Physical Review B* 50: 590–593, © 1994 APS.

Fig. 8 Bottom: photoemission spectra of three-dimensional and two-dimensional metals exhibit a clear edge at the Fermi level, as predicted for Fermi liquids. Top: one-dimensional metals sometimes depart from this framework. Reproduced from Perfetti L (2002) Ph.D. thesis, EPFL: Lausanne.

Conclusion

Forty years after the development of the theoretical background for the photoelectric effect, the advent of ultrahigh-vacuum techniques solved the problem of surface contamination and opened the door to the leading role of photoemission techniques as probes of valence electrons in solids. In their simplest versions, such techniques explored the properties of the electronic states in the specimen, specifically the density of states with angle-averaged photoemission and the band structure of crystalline solids with angle-resolved photoemission.

The advent of synchrotron sources and, more recently, of free electron lasers boosted the capabilities of valence photoemission beyond this limited domain. This led to a variety of novel approaches including spin-polarized photoemission, time-resolved photoemission, spectromicroscopy, constant initial state (CIS) spectroscopy, the study of photoemission resonances and others.

After the discovery of high-temperature superconductors, high-energy resolution photoemission started to explore phenomena beyond the Fermi-liquid framework. This was made possible by a concentrated and successful effort to improve the energy resolution. The results most notably included the detection and analysis of the high-temperature superconducting gap, in particular its spatial asymmetry.

Abstract

This article describes impedance spectroscopy and its relationship to dielectric properties (IS/DS). Impedance spectroscopy is generally interpreted in terms of equivalent circuits that can represent different electrical paths present in a material or device. Details about the simplest equivalent circuit models that can be used to interpret results is presented as well as suggestions on how to maximize the information that one can obtain from the ac measurements. IS/DS is often used to determine the conductivity of many materials and devices and therefore it is important to be able to separate effects caused by surface phenomena from bulk processes.

[☆]*Change History:* August 2022. RA Gerhardt updated the article has been substantially revised and only a few of the original images are included. And have referenced the original article published in 2005 multiple times.

Graphical Abstract

(A) Real and Imaginary impedance and complex plot for an RC circuit, (B) Real and Imaginary impedance for an RL circuit, (C) Complex impedance plots for two parallel RC circuits in series where the capacitors are three orders of magnitude apart and the resistances vary as shown, (D) Complex impedance, complex permittivity, real and imaginary permittivity for a material with four different resistivity values and the same relaxation ratio.

Glossary

Cole-Cole plots This is the name given to plots of imaginary permittivity vs. real permittivity (mostly ϵ'' vs. ϵ') which can also be labeled as complex permittivity plots or frequency explicit plots. The original name came from a publication by Cole and Cole (1942) that described excursions from an ideal Debye relaxation behavior which result in complex ϵ^* with the center of the semicircle origin sitting $\alpha\pi/2$ below the x-axis.

Frequency explicit plots Often referred to as Bode plots where one plots the real or imaginary component of a given function versus the frequency on a log scale.

IS/DS This is the combined approach of analyzing impedance spectra in terms of both impedance spectroscopy and dielectric spectroscopy.

Multiphase analysis In order to capture all of the phenomena that may be present in a material or device, it is necessary to conduct multiphase analysis to ensure that all processes are detected. Multiphase analysis refers to obtaining fitted data in terms of impedance, admittance, permittivity and electric modulus simultaneously. Data fitting using only impedance plane can often miss details only revealed by the other functions.

Negative dielectric constant All materials can undergo polarization of different charged species under the application of an electric field. Negative dielectric constant is mostly observed in conducting materials such as metals and highly conducting semiconductors, metamaterials and piezoelectrics. See some examples that are given in the text.

Nyquist plots This is the name given to plots of the imaginary vs real component (mostly Z'' vs. Z') which can also be labeled as complex impedance plots or frequency implicit plots.

Quadrants Since impedance and dielectric properties consist of real and imaginary parts, it is possible for the properties to carry a sign. By convention, parallel RC circuits are displayed in the 1st quadrant making sure to label the y-axis with a negative sign. In contrast, parallel RL circuits show up in the 4th quadrant where both the real and imaginary components are both positive.

Relaxation ratio This is the ratio that relates the low frequency permittivity to the high frequency permittivity that can help monitor the effect of the presence of a dipolar relaxation or a molecular relaxation in a Debye type process (Cao and Gerhardt, 1990) and its transformation to long range conductivity (Gerhardt, 1994). The relaxation ratio r can be written as $r = C_2/C_1 = \epsilon_s/\epsilon_\infty$. It is different from $\Delta\epsilon = \epsilon_s - \epsilon_\infty$.

Space-charge behavior Space charge behavior may occur at any interface in a given material or device. The most common space charge phenomena refer to electrode contact space charge behavior caused by ohmic or non-ohmic Schottky type interfaces. Space charge type interfaces may also appear in multilayer films, polycrystalline materials, at the filler-matrix interfaces in polymer and ceramic composites as well as in semiconductors and metamaterials.

Time constant This is a number which is characteristic of a given electrical/optical/magnetic process that gives rise to a relaxation or resonance and can be obtained via equivalent circuit data fitting or knowledge of the expected complex resistivity, complex dielectric properties (including index of refraction) or complex magnetic properties. See simulations in the supplementary for some examples.

Introduction

Impedance Spectroscopy is a technique that has seen revolutionary changes in the last 50 years as a result of the development of computer automation, swift data analysis, design of better frequency response analyzers and the ability to acquire data over many different frequency ranges (Gerhardt, 2005; Gerhardt, 2022). Most commercially available equipment today can collect real and imaginary impedance data from frequencies as low as a few microHertz and as high as a few GHz. Due to the large variance in material resistivities (e.g., $\rho > 10^{12} \Omega\text{-cm}$ for insulators and $< 10^{-3} \Omega\text{-cm}$ for semiconductors), different manufacturers specialize in the characterization of specific material types and the equipment specifications can vary widely.

Impedance spectroscopy, also referred to as IS/DS because of its close relationship to dielectric spectroscopy (Gerhardt, 1994), involves the measurement of the current (I), voltage (V) and phase angle (θ) over a wide frequency range so that the impedance vector (Z^*) may be defined as follows:

$$Z^*(\omega) = V(\omega)/I(\omega) \quad (1)$$

where $V(\omega) = V_m \sin(\omega t)$, $I(\omega) = I_m \sin(\omega t + \theta)$, $\omega = 2\pi f$, f is the linear frequency and θ is the phase difference between the current and the voltage.

Measurements can also be carried out in the time domain and then Fourier transformed into the frequency domain (Macdonald, 1987). Each measurement mode has advantages and disadvantages. The frequency domain is ideally suited for determining the steady state response of the object under test whereas the time domain is better suited for detecting time-dependent phenomena. This article will focus on frequency domain measurements.

Equivalent circuits

It is customary to analyze the measured impedance response in terms of the possible equivalent circuit components that can give rise to the frequency response observed. The circuit elements of interest are capacitors, represented by C, resistors, represented by R, and inductors, represented by L. Most dielectric materials can be represented by a parallel RC circuit, whereas others are better represented by a series RC circuit. The presence of magnetic components introduces inductive elements, and one may expect that series or parallel RL circuits may represent such materials (Gerhardt, 2005).

It is useful to remember that if elements are in series, it is easier to write the impedance response. On the other hand, if the circuit elements are in parallel, it is more convenient to write the admittance and then convert it to the impedance. For example, the impedance of a series RC circuit is written as:

$$Z^* = R + [1/j\omega C] \quad (2)$$

whereas the impedance of a parallel RC circuit is given by:

$$Z^* = 1/Y^* \quad (3)$$

where $Y^* = (1/R) + j\omega C$.

Most modern equipment includes some version of software that can be used to fit the most appropriate equivalent circuit to the experimentally measured results. However, the reader is urged to consider the physical mechanisms that may have contributed to the experimental data before concluding that a derived R or C is representative of the bulk of the material or device being measured (See section on data analysis below for more details).

Table 1 lists the simplest equivalent circuits and their corresponding impedance equations (modified from Gerhardt, 2005). Data acquired can be plotted in terms of frequency explicit and frequency implicit impedance plots. The frequency implicit plots are better known as complex plots because the imaginary impedance is plotted versus the real impedance. These plots are often referred to as Nyquist plots or Cole-Cole plots and result in the formation of semicircles only under certain conditions. Table 1 also displays complex plots for each of the simplest equivalent circuits listed and are drawn with imaginary impedance in the first quadrant where Z'' is negative as shown. Note that not all circuits display semicircles and when they do they can appear in any of the four quadrants (more about this later). Frequency explicit plots are often referred to as Bode plots. They are just simply real (Z') or imaginary impedance (Z'') plotted versus frequency. The magnitude of the impedance vector, which is equal to,

$$|Z^*| = [Z'^2 + Z''^2]^{1/2} \quad (4)$$

and the phase angle θ are also plotted versus the measured frequency. The magnitude of the impedance vector is useful for quickly assessing the presence of resistive components (flat with frequency), capacitive components (decrease with increasing frequency) and inductive components (increase with increasing frequency) (Gerhardt, 2013). See Fig. 1A for representative frequency explicit plots for a perfect resistor, a perfect capacitor and a perfect inductor as well as the corresponding phase angle vs frequency shown in Fig. 1B (modified from Gerhardt, 2022). Phase angles are zero for resistors, -90 degrees for capacitors and $+90$ degrees for inductors and should follow the same designation of the four quadrants.

Table 1 Equivalent circuits for selected circuits with impedance equations and complex plots.

Resistor		$Z^* = R$	
Capacitor		$Z^* = 1/j\omega C$	
Inductor		$Z^* = j\omega L$	
RC parallel		$Z^* = 1/(1/R + j\omega C)$	
RC series		$Z^* = R + (1/j\omega C)$	
RL parallel		$Z^* = 1/(1/R + 1/j\omega L)$	
RL series		$Z^* = R + j\omega L$	
LC series		$Z^* = j\omega L + 1/j\omega C$	
LC parallel		$Z^* = 1/(1/j\omega L + j\omega C)$	
LCR series		$Z^* = \omega L + (1/j\omega C) + R$

Modified from Gerhardt RA (2022) What is impedance and dielectric spectroscopy? *IEEE Instrumentation and Measurement Magazine*, 14–20.

Time constants and frequency dependence

In reality one will never experimentally observe single circuit elements by themselves but instead they will appear in combination with other circuit elements as depicted in Table 1. One of the most important concepts one needs to understand is that parallel RC and parallel RL circuits will always show a semicircle in the complex impedance plane when their time constants $\tau = R_p C_p$ or L_p / R_p allow it to appear within the frequency range of the measurements. By established convention, a parallel RC circuit will display a semicircle in the first quadrant if the imaginary Z'' axis is labeled as negative. In contrast, a parallel RL circuit will display an upside down semicircle in the fourth quadrant (Gerhardt, 2005). Fig. 2 displays the Nyquist plots once again and the corresponding real and imaginary impedance plotted vs log frequency (f) highlighting the parallel RC and parallel RL time constants, where the apex of the semicircle is equal to $\omega\tau =$, $\omega = 2\pi f_p$, and f_p is the frequency where a peak will appear in the imaginary impedance. In contrast, series RC and series RL circuits will never show a semicircle in the complex impedance plane (as shown in Table 1 and described by Gerhardt, 2005). Instead, they will show a semicircle in the complex admittance plane with time constants $\tau = R_s C_s$ or L_s / R_s for the series RC circuit and the series RL circuit respectively.

Fig. 3 displays the complex impedance, complex admittance as well as the real and imaginary admittance plotted versus log frequency for the series RC, series RL and series RLC circuits. The RLC circuit shows both capacitive and inductive behavior as in the series RC and series RL circuit. As a result, the imaginary part of the RC and RL circuits will carry opposite signs as shown in Fig. 3C, F and I. Additionally, the RLC circuit does have an additional time constant associated with the LC combination which is equal to $\tau_{LC} = 1/(LC)^{1/2}$ which provides the frequency where the transition from the series RC or RL occurs (not shown because LC circuits do not result in semicircles) (Gerhardt, to be published).

Temperature dependence and conductivity curves

A generalized equation for conductivity (σ) for all types of materials (Schaffer et al., 1999; Buchanan, 2004) relates the number of charge carriers (N) to their charge (q) and their mobility (μ) as in

$$\sigma = \sum_{i=1}^n (N_i |q_i| \mu_i) \quad (5)$$

where i refers to the i^{th} charge carrier. Since conductivity is inversely proportional to resistivity, we often use the value of resistance R obtained through impedance or admittance measurements to calculate the conductivity by incorporating the geometrical dimensions of the sample (Bauerle, 1969). Note that impedance and admittance do not always represent the same physical mechanism as will be described in more detail later. More often, the activation energy for conduction, in a given system, is obtained by taking the intercept of the impedance or admittance semicircle with the real axis, as displayed in Figs. 2A and 3B, as a function of temperature and then converting that to conductivity and plotting the calculated conductivity versus inverse temperature (for semiconductors and insulators or resistivity vs. T for metallic conductors). Either type of analysis is only accurate when the resistance and capacitance of the electrical processes being measured are both independent of frequency. A truly bulk response will always have constant R and C at a given temperature. This is not the case for space charge polarization under biasing conditions or diffusion controlled processes. In both of these cases, the number of mobile charge carriers will change the values of R and may also affect the value of C .

Fig. 2 Representative complex impedance, real impedance and imaginary impedance for (A) a parallel RC circuit, (B) a series RC circuit.

Furthermore, many materials and devices contain more than one electrical path and one cannot immediately assign the intercept of the semicircle on the impedance plane as given in Figs. 2 and 3 to the bulk behavior one is seeking to obtain. It is necessary to determine if the process giving rise to such semicircles is truly due to the bulk of the material by obtaining the geometric capacitance/inductance using the time constant formalisms given in the previous section. Additionally, one needs to conduct 4-probe dc measurements to ensure that the values obtained refer to the dc conductivity (Wang and Nowick, 1980) of the phase of interest and not to contact effects with the electrode or grain boundary phases in the material.

In the absence of impurities or other factors that could affect the measured conductivity, the temperature dependence is given by the temperature dependencies listed in Table 2 (compiled from Schaffer et al., 1999, Buchanan, 2004). For metallic materials, it is customary to use the resistivity $\rho(T)$ at a given temperature in terms of the coefficient of resistivity α at a reference temperature T_0 with the reference resistivity ρ_0 . The conductivity of semiconductors is related to the size of the band gap (E_g) and the conductivity of insulators can depend on the diffusivity D_{ion} of the ionic species that dominates the process which may control the transport of

Fig. 3 Representative complex impedance plots, complex admittance plots and imaginary admittance plots for a series RC circuit (A, B and C), a series RL circuit (D, E and F) and a series RLC circuit (G, H and I).

Table 2 Conductivity for different material types.

Type	Charge carriers	Carrier charge	Mobility	Temperature dependence
Metallic	Electrons, Constant N	Constant q	$\mu \propto 1/T$	$\rho_T = \rho_0 [1 + \alpha (T - T_0)]$
Semiconductor	Electrons and holes	$q_e = q_h$	$\mu_e \propto 1/T$	$\sigma_{\text{int}} = \sigma_{0,\text{in}} \exp.[-E_g/2kT]$
Intrinsic	$N_e = N_h$		$\mu_h \propto 1/T$	$\sigma_{n\text{-type}} = \sigma_n \exp.-(E_g - E_d/kT)$
Extrinsic	$N = N_0 \exp.[-E_g/2kT]$			$\sigma_{p\text{-type}} = \sigma_p \exp.-(E_a/kT)$
	$N_e = N_d \exp. -(E_g - E_d)/kT$			
	$N_h = N_a \exp. -E_a/kT$			
Insulator	Electrons, holes	q_e	$\mu_e \propto 1/T$	
Electronic carriers		q_h	$\mu_h \propto 1/T$	
Ionic carriers	Anions, cations	q_{ion}	$\mu_{\text{ion}} = D_{\text{ion}} q_{\text{ion}}/kT$	$\sigma \propto D_0 \exp. (-Q/RT)$

that ion. There are of course many additional more complex dependences associated with the presence of controlled impurities such as temperatures where donors and acceptors affect the properties of semiconductors (Kasap, 1997), defect association which can modify the conductivity behavior of ionic conductors (Gerhardt-Anderson and Nowick, 1981; Barsoum, 2019), the formation of polarons when electronic defects attach themselves to ionic defects (Austin and Mott, 1969) as well as Cooper pairs in superconductors (Varlamov et al., 1999) and other types of charge carriers in more complex cases which are discussed in more detail in other chapters of the encyclopedia.

Multiple parallel processes appearing on the impedance plane

Before moving onto describing the relationship of impedance with dielectric permittivity, it is important to first discuss what is expected to happen when more than one process shows up in the measured spectra. The presence of more than one semicircle in the complex impedance plane generally signifies the presence of more than one parallel RC circuit in series (Gerhardt and Nowick, 1986; Gerhardt, 2005). However, as seen earlier, it is also possible to see semicircles due to parallel RL circuits and other combinations although semicircles due to parallel RL will appear in the fourth quadrant as shown in Fig. 2B (Gerhardt, 2013; Muhlbauer et al., 2013). Reasons for getting more than one semicircle in the complex impedance plane can include: (1) a solid state ionic material with different response at the grain boundaries than within the bulk grains (Gerhardt et al., 1986; Guo and Maier, 2001); (2) a semiconducting material with space charge polarization at the electrode/material interface (Bertram and Gerhardt, 2009; Snaith and Grätzel, 2007); and (3) the presence of inductive behavior in an otherwise conducting material (Muhlbauer et al., 2013) and (4) bulk response and interfacial responses in multiphase systems (Bertram and Gerhardt, 2011a,b; Pruyun and Gerhardt, 2015).

In Fig. 4, different combinations of two parallel RC circuits in series are presented where the capacitances of process 1 and process 2 are kept constant at 1 pF and 1 nF respectively. The physical meaning of each of these circuit elements is, however, quite different for each of these cases. Table 3 lists some of the possible physical processes that may be responsible for the multiple semicircles obtained. In Fig. 4A the case where $R_1 > R_2$ is depicted whereas in Fig. 4B $R_1 = R_2$ and in Fig. 4C $R_1 < R_2$. In Fig. 4D, which can represent either the case where $R_1 \gg R_2$ or $R_1 \ll R_2$, one can only detect a single semicircle even though we started out with two processes. This makes it clear that when the difference between the relaxation times of the two processes present is small, one of the processes may be overshadowed by the other in the impedance plane (Gerhardt, 2005). It is more common to see the case of $R_1 > R_2$ nowadays (Fig. 4A) that most everyone works with nanocrystalline materials (Maier, 2004; Kosacki and Anderson, 2001) than it was earlier (Gerhardt and Nowick, 1986) when the bulk grains were on the micrometer scale and the grain boundaries were expected to be on the nanometer scale (Fig. 4C). Even if the two regions have the same resistance as was reported for YSZ materials due the high content of the dopants (Gerhardt-Anderson and Nowick, 1985), differences in the capacitance would still give rise to both semicircle being visible as seen in Fig. 4B. A similar situation will occur if we were to fix the resistance value and vary the capacitance (not shown). In fact, working with nanomaterials has made it more difficult to separate the grain boundary response from that of the bulk since the capacitances of the grain boundaries are on the same order of magnitude as those of the bulk nanograins, in contrast to earlier work which focused on micron-sized specimens that gave rise to capacitances that were three orders of magnitude apart (Gerhardt et al., 1986). All of these figures illustrate that only looking at the impedance plane may prevent identification of the presence of a second process. It may also be possible to reveal the presence of more than one process when the magnitude of the spectra are quite different, if one uses logarithmic scales, as suggested by Jonscher (1983) and demonstrated by Muhlbauer and Gerhardt (2013).

When making measurements of a semiconducting or a conducting material, it is important to pay attention to whether the electrode contact is ohmic or not (Ou et al., 2003; Hwang et al., 1997). If the electrode contact is non-ohmic or the charge transfer between the semiconductor and the electrode is inefficient, then an additional semicircle may be observed, which may be related to the space charge polarization at that interface and not be representative of the bulk of the material one is trying to characterize. Fig. 5A and B show the complex impedance graphs simulations for a semi-insulating material in contact with a blocking electrode (after Etsell and Flengas, 1970). Fig. 5A shows the response for a given size electrode for the same material with the same dimensions where the time constant does not change but the size of the semicircle does (Kumar and Gerhardt, 2012), whereas

Fig. 4 (A) Two parallel RC circuits in series is the simplest equivalent circuit needed to represent the various two physical process systems described in Table 3. In all cases, $C_1 = 1$ pF and $C_2 = 1$ nF. (A) Complex impedance plot for a two-process system where $R_2 < R_1$. (B) Complex impedance for $R_1 = R_2$. (C) Complex impedance plot for a two process system where $R_2 > R_1$. (D) Complex impedance plot for a two-process system where $R_2 \gg R_1$. Note that R_1 is not easily detected in this case and that the impedance plot is dominated by R_2 . Modified from Gerhardt RA (2005) Impedance spectroscopy and mobility spectra. In: Bassani G, Liedl G, Wyder P (Eds.). *Encyclopedia of Condensed Matter Physics*. Elsevier Press, pp. 350–363.

Fig. 5B displays the effect of changing the electrode size for a given material which affects the semicircle due to the electrode but not the response of the bulk material (Mebane and Gerhardt, 2006). Another way to detect these changes is to use a superimposed dc bias which will decrease the size of a blocking contact (Bertram and Gerhardt, 2009).

In Fig. 6, combinations of parallel RC and parallel RL circuits in series are displayed (modified from Gerhardt, 2013). These spectra are not as commonly observed as the parallel RC circuits in series described in the preceding paragraphs but they have become a lot more common place when characterizing conducting nanomaterials such as carbon nanotubes (Muhlbauer et al., 2013; Muhlbauer and Gerhardt, 2013; Muhlbauer et al., 2014; Muhlbauer and Gerhardt, 2021) and ITO thin films (Joshi and Gerhardt, 2013; Xia and Gerhardt, 2016) as well as solar cell devices (Panigrahi et al., 2016) and even memristors (Bisquert, 2021; Bou and Bisquert, 2021). In Fig. 6, the graphs were chosen to illustrate the effect of changing the R values so that we can compare the case where $R_{RL} = R_{RC}$ to when the resistance is larger for the RL circuit vs the RC circuit ($R_{RL} > R_{RC}$) and viceversa ($R_{RL} < R_{RC}$). It is clear that when the two R values are the same, a complete impedance circle is always observed (Gerhardt, 2013). These graphs can truly change in appearance quite rapidly so only cases where the two semicircles can be seen are shown. Fig. 6 shows arrows to indicate which way frequency increases. When $R_{RL} < R_{RC}$, it can be seen that the smaller semicircle related to the R_{RL} appears at low frequencies when the time constant $\tau_{RL} > \tau_{RC}$ whereas it appears at higher frequencies when the time constants are

Table 3 Relationships between dielectric functions.

$Z^* = 1/JWC_0\epsilon^*$	$E^* = 1/JWC_0Z^*$
$Y^* = JWC_0\epsilon^*$	$Y^* = 1/Z^*$
$M^* = 1/\epsilon^*$	$M^* = JWC_0Z^*$
$TAN \delta = \epsilon''/\epsilon'$	$TAN \delta = Z''/ZZ'$

Fig. 5 (A) displays a situation where a blocking electrode is used and the size of the measured semicircle changes with it overshadowing the bulk response. (B) Case where both bulk and space charge due to blocking electrode are visible but can be minimized by varying electrode size which shows that only space charge semicircle is affected.

$\tau_{RL} < \tau_{RC}$ (Gerhardt, 2013). The opposite is observed for when $R_{RL} > R_{RC}$ where the smaller semicircle related to the R_{RC} appears at lower frequencies when the time constant $\tau_{RL} < \tau_{RC}$ while the smaller semicircle due to R_{RC} appears at higher frequencies when $\tau_{RL} > \tau_{RC}$. The reader is referred to the online version where a movie is displayed that presents a more gradual change between these very different cases.

Microscopic interpretation

If one is interested in determining what electrical process has given rise to a particular set of impedance spectra, it is useful to remember that all materials are made up of charged entities at various length scales (see Fig. 7 for an example). At the atomic level, we have protons and electrons. At the molecular level, we may have anions, cations or charged molecules. At the nano- meso- and micro-structural levels within a single material, we may also have charged interfaces (space charge at electrode surface or internal interfaces). The interface between the contacting electrode and the material surface often results in space charge polarization (Kao, 2004). Hence, the impedance response measured is dictated by the total number of impediments to the current flow that an ac signal encounters on its way from the high to the low voltage electrode. The impedance response measured is then a function of the frequency of the applied field, how that field interacts with each polarization process present in the material, and whether it is commensurate with the dimensions of the permanent or temporary dipoles formed and the strength of the signal.

Polarization mechanisms

Fig. 8 schematically displays the real and imaginary permittivity response of a material as a function of the applied frequency (Gerhardt, 2005). Upon the application of an electric field, atomic or electronic polarization are easily detectable in the optical frequency range, and this results in the resonance response displayed. Polarization strength is proportional to the number of electrons present (Kao, 2004) and is governed by the equation below

$$P = Zqd \quad (6)$$

where Z is atomic number, q is the charge constant $= 1.609 \times 10^{-19}$ coulombs/m and d is the distance.

Fig. 6 Effect of resistance when a parallel RC circuit is followed by a parallel RL circuit. When $R_1 = R_2$, one obtains a complete circle whereas the location of each RC or RL component varies depending on whether the time constant for the RC circuit is higher or lower than that of the RL circuit. In: Bassani G, Liedl G, Wyder P (Eds.). *Encyclopedia of Condensed Matter Physics*. Elsevier Press, pp. 350–363.

At the molecular level, dipole polarization can be due to temporary or permanent dipoles present in a material. Permanent dipoles are present in those materials that possess a different center of positive charge from that of a negative charge. This includes all ferroelectrics below their Curie temperature, all polar polymer molecules, and all polar liquids such as water. It may also occur by aliovalent doping of compounds which results in specific defects (Chadwick, 2007; Anderson and Nowick, 1981; Nowick and Berry, 1972). Temporary dipoles may occur in weakly bound polymers (Block and North, 1970) or in the electrostatic attachment of nanowires to patterned substrates (Kumar et al., 2005). Molecular temporary dipoles also occur in ionically bonded materials, such as many oxides and fluorides (Figuroa et al., 1984).

Space charge polarization occurs whenever the electrical response at an interface is dominated by pile up of charge carriers at that interface (Kao, 2004). This commonly occurs at the interface between the contacting electrode and the material under test, and is

often assumed to only occur at very low frequencies. If the electrode contact is non-ohmic or if the charge transfer resistance is high, the space charge polarization will overshadow any other processes that may be present in the material. Space charge polarization may also occur at the interfaces between grains of phases with very different electrical properties (Balke et al., 2010; Figueroa et al., 1984) or at the grain boundaries of a single-phase material, if the defect concentration is high or if there is segregation of impurities into or away from the boundaries (Gerhardt et al., 1986; Guo and Maier, 2001; Hughes et al., 2018). Space charge polarization at the interfaces between two different materials is generally expressed in terms of the Maxwell-Wagner two-layer condenser model (Von Hippel, 1954). These equations will be discussed in the multiple relaxation process section.

Space charge polarization at electrode-material interfaces is often diffusive in nature and can be represented by the Warburg impedance (Barbero and Lelidis, 2017). This gives rise to a linear dependence of the conductivity on the frequency of the measurement, as described in the equation below:

$$Z^* = [A/(D\omega)^s](1 - j) \quad (7)$$

where A is a constant related to the valence state of the diffusing species and the concentration gradient, and s represents the diffusion exponent. For perfect diffusion controlled response, $s = 1/2$. This is often seen as a straight line at 45 degrees from the real impedance axis (Macdonald, 1987; Muralidharan, 1997). Many studies dealing with diffusion controlled interfaces have been studied in fuel cells (Kulikovsky, 2016), batteries (Cruz-Manzo and Greenwood, 2020), solar cells (Omar and Abdullah, 2014; Romero et al., 2019) and supercapacitors (Buller et al., 2005) where liquid electrolytes are often used to make electrical contact.

Relaxation and resonance frequency spectra

The Debye relaxation

The frequency dispersion that allows transformation of the dielectric response from one polarization mechanism to another is known as dielectric relaxation. The Debye equation describes this for essentially all relaxation processes even though it was originally developed to represent dielectric relaxation in polar liquids (Hill and Dissado, 1985):

$$\varepsilon^* = \varepsilon_\infty + (\varepsilon_s - \varepsilon_\infty) / [1 + j\omega\tau_D] \quad (8)$$

where ε_∞ represents the high frequency dielectric permittivity, ε_s is the lowest frequency dielectric permittivity (sometimes referred to as the static permittivity), ω is the angular frequency and τ_D the relaxation time for the Debye process.

The frequency implicit complex permittivity graphs and the real and imaginary parts of the permittivity are plotted vs frequency in Fig. 9 (modified from Cao and Gerhardt, 1990). It is clear that a complete semicircle is observed for the Debye process while the real part of permittivity displays a sigmoidal shaped curve that changes from the low frequency ε_s to the high frequency ε_∞ that results in the formation of an imaginary ε'' peak in the frequency explicit graph, where the Debye time constant can be obtained by taking $\omega\tau_D = 1$ and $\omega = 2\pi f_p$ at the apex of the complex permittivity semicircle and identify the frequency at which it will appear in

Fig. 9 Simulated complex permittivity, real and imaginary permittivity for the ideal Debye case. Modified from Cao W, Gerhardt R (1990) Calculation of various relaxation times and conductivity for a single dielectric relaxation process. *Solid State Ionics* 42: 213–221.

the imaginary permittivity graph. This same equation can be used to represent any of the relaxation processes that were depicted in Fig. 8 making sure to replace to use different values of the high frequency ϵ_∞ and the low frequency ϵ_s for the different processes.

Cole-Cole, Davidson-Cole and Havriliak-Negami relaxations

Since most materials do not behave in an ideal manner, a number of modifications to the Debye equation have been taken. Cole-Cole were the first to have modified the Debye equation to account for deviations from the ideal Debye response. Cole and Cole (1942) introduced the α parameter as follows:

$$\epsilon^* = \epsilon_\infty + (\epsilon_s - \epsilon_\infty) / [1 + (j\omega\tau_D)^{1-\alpha}] \quad (9)$$

where $\alpha < 1$ shows up as a depression angle $\alpha\pi/2$ below the real ϵ' axis. Davidson and Cole introduced the β parameter, which accounts for deviations from ideality in the highest frequency region of the Debye relaxation (Davidson and Cole, 1950) that shows up as an inclined $\beta\pi/2$. This modification is written as follows:

$$\epsilon^* = \epsilon_\infty + (\epsilon_s - \epsilon_\infty) / [1 + j\omega\tau]^\beta \quad (10)$$

To account for both spreading of the relaxation time and deviations from ideality at high frequency, Havriliak and Negami (1967) combined the two parameters, as shown below:

$$\epsilon^* = \epsilon_\infty + (\epsilon_s - \epsilon_\infty) / [1 + (j\omega\tau)^{1-\alpha}]^\beta \quad (11)$$

The Havriliak and Negami equation is often used to characterize dielectric polymers because their response can be quite non-ideal (Havriliak and Negami, 1967). The differences between the Debye, Cole-Cole and Davidson-Cole relaxation equations are illustrated in Fig. 10. Some of these deviations can be accounted for by the use of the constant phase element (CPE), which is often used to account for non-ideal behavior (Brug et al., 1984; Boukamp, 2020).

Resonance behavior

Resonance spectra are hardly ever discussed in the context of impedance spectroscopy. This is because ionic and electronic resonance generally occur at frequencies near the optical range and are best detected with optical spectroscopic methods such as IR, UV and visible spectroscopy methods (Zhang, 2009) as well as spectroscopic ellipsometry (Fujiwara, 2007). NMR (Hatada and Kitayama, 2004) and EPR (Goldfarb and Stoll, 2018) methods are also superb at detecting ionic resonances. Nevertheless, it is possible to observe resonance phenomena when making impedance measurements. Resonance behavior that occurs at the lower frequencies of impedance measurements is normally associated with parasitics in the measurement circuitry but may also be due to non-linear response of materials such as in ferroelectrics (Gerhardt et al., 1996) and ferromagnetics (Valenzuela, 2001) as well as in metamaterials applications (Li et al., 2014). An equation that can generate a resonance response is given by

$$\epsilon^* = \epsilon'_\infty + \frac{1}{2} (\epsilon'_s - \epsilon'_\infty) / [(1 - (\omega/\omega_{res})) + (\beta/\omega_{res})] \quad (12)$$

where ϵ'_s and ϵ'_∞ are the permittivities at frequencies much lower and much higher than the resonant frequency ω_{res} , and β represents the strength of the restoring force that gives rise to resonance (Jonscher, 1983). Fig. 11 displays the frequency explicit and frequency implicit graphs of the dielectric resonance equations for two different cases. It is to be noted when a dielectric resonance occurs, one gets to observe a negative dielectric constant at certain frequencies as shown in Fig. 11 (Jonscher, 1983). This also occurs for transitions in piezoelectrics (Appleby et al., 2014) or where there is a barrier being overcome (Joshi et al., 2020).

Various representations of the dielectric function

A fact not often recognized is that the dielectric relaxation equation originally developed by Debye for relaxation in polar liquids provides another way to interpret impedance data (Gerhardt, 2005). This is possible because dielectric permittivity is inversely related to impedance, as shown below:

$$Z^* = 1/j\omega C_0 \epsilon_r^* \quad (13)$$

Therefore, it follows that measured impedance data can be converted into permittivity and vice-versa provided that the geometric capacitance, C_0 , of the sample measured is known and is multiplied by the relative permittivity, ϵ_r^* . It needs to be mentioned that many references do not use the 'r' subscript although the value needs to be unitless because it is normalized by the geometric capacitance. Recalling that admittance, Y^* , is the inverse of impedance and that electric modulus, M^* , is the inverse of permittivity, it then becomes possible to analyze the SAME measured data in four different formalisms without the use of any adjustable parameters (Cao and Gerhardt, 1990). Table 4 lists all the important relationships between these four dielectric functions. Performing the conversions mentioned is advantageous because polarization or conductivity processes that may be hidden in the impedance, for example, may become fully detectable in the admittance plane or permittivity plane because their frequency dependence are different (Gerhardt to be published).

As was shown in Fig. 3A and D, the complex impedance for a series RC circuit and a series RL circuit do not show semicircles. Instead, they show semicircles in the complex admittance graphs, displayed in Fig. 3B and E. The main difference being the quadrant in which they appear. For the circuits containing a capacitance and a resistance, they appear in the first quadrant for the impedance for the parallel RC (see Fig. 2A) but the fourth quadrant for the admittance for the series RC (See Fig. 3B), whereas for those containing an inductance, they appear in the fourth quadrant for the parallel RL impedance (Fig. 2B) but the first quadrant for the series RL admittance (see Fig. 3E).

It turns out that when we observe semicircles in any of the complex graphs, they are always paired with peaks in their corresponding imaginary functions as was already shown in Figs. 2 and 3 for the parallel and series RC and RL circuits and Fig. 9 for the Debye relaxation. When the semicircles represent the same physical processes, then they will show peaks in related imaginary

Table 4 Possible physical processes for two parallel RC circuits in series.

	R_1	C_1	R_2	C_2
Ionic conductor	Bulk	Bulk	Grain to grain interface	Grain to grain interface
Semiconductor	Bulk	Bulk	Electrode interface	Electrode interface
Multiphase 1	Bulk	Bulk	Interphase	Interphase
			Boundary	Boundary
Multiphase 2	Main phase	Main phase	Second phase	Second phase

functions. For example, for long range dc conductivity, the frequency at which the peaks can appear in the imaginary functions will be the same for the impedance and the electric modulus so that $f_{Z''} = f_{M''}$ (Gerhardt, 1994), whereas for ac conductivity $f_{Y''} = f_{\epsilon''}$ (Cao and Gerhardt, 1990; Gerhardt, 1994). When only dielectric relaxation occurs and no measurable conductivity can be obtained, then the only functions of interest will be ϵ'' , $\tan \delta$ and M'' (Gerhardt, 1994). There is not enough room to describe the many different processes that may occur in all types of materials and devices in this short introductory article. Nevertheless, the importance of using multiplane analysis cannot be ignored as it is often the only way for the analysis to reveal all of the possible processes present in a given sample or device. Such an analysis will often reveal the true richness of the IS/DS measurements by helping identify electrical/optical/magnetic processes occurring in many materials and devices. A few examples will be given in the multiple processes section that will demonstrate that each equivalent circuit type will have their own unique signatures, not just those described in the Debye relaxation papers (Cao and Gerhardt, 1990; Gerhardt, 1994). In fact, Hodge, Ingram and West gave some examples of multilayer samples in the 70s (Hodge et al., 1976). Several review articles will be appearing in the near future focusing on several of the many additional electrical/optical/magnetic applications.

While conversions to all of the different functions can be made without any adjustable parameters, it should be emphasized that these mathematical transformations need to be done with caution as the data on either extreme of the frequency range of a given impedance analyzer will tend to carry a higher error (Boukamp, 1993). Hence, taking the inverse can amplify the size of the errors. Nevertheless, it is an extremely useful tool for determining the most appropriate model that can help identify the relaxation process or processes present more easily than just looking at one of the functions. Moreover, once the relaxation process has been identified, the data can then be used to obtain the activation energy for that particular process.

Multiplane analysis of several multiple process combinations

If we refer back to Figs. 4–6, it should not be surprising to realize that most experimentally measured spectra will be made up of more than one relaxation process. Additional examples can include: (1) a Debye-type dielectric polarization process, (2) A Debye process with a parallel leakage current; (3) a simple semi-insulating process represented by a parallel RC circuit, (4) a simple conducting process represented by a parallel RL circuit, (5) a solid state ionic material with different response at the grain boundaries than within the bulk grains, (6) a semiconducting material with space charge polarization at the electrode/material interface, (7) a highly conducting nanomaterial and (8) bulk and interfacial responses of multiphase systems. Before describing each of these different processes, we need to describe how to obtain the activation energy via the temperature dependences observed.

Temperature dependence

Most relaxation/conductivity phenomena in insulators, ionic conductors and semiconductors are thermally activated (Nowick and Berry, 1972). As a result, the relaxation time can be expressed in terms of an Arrhenius-type temperature dependence:

$$\tau = \tau_0 \exp.(E/kT) \quad (14)$$

where τ_0 is the relaxation time at infinite temperature, E is the activation energy for the relaxation process in eV, k is Boltzmann's constant and T is temperature in degrees Kelvin. In addition, when a relaxation process occurs, $\omega_{\max}\tau = 1$ regardless of which function it appears in. Therefore, one can use the frequency at which a peak occurs at a given temperature as a way to determine the activation energy for that process. Fig. 12A schematically displays a dielectric loss ($\tan \delta = \epsilon''/\epsilon'$) process that changes peak frequency as temperature is changed. The linearized version of Eq. (14) converted to peak frequency f_p is used to obtain the activation energy as depicted in Fig. 12B.

Similarly, conductivity processes may display peaks in the imaginary impedance or imaginary admittance, which could then be used to estimate the activation energy for those processes in the same fashion as described above. The supplementary videos show several cases of the time constants for a parallel RC, a parallel RL, two parallel RC processes in series and two parallel RL processes in series to show how the time constant can affect the phase angle and the imaginary part of the impedance. More often, the activation energy for conduction, in a given system, is obtained by taking the intercept of the impedance semicircle with the real axis, as displayed in Figs. 2–6, and converting that to conductivity after taking the geometric dimensions into account and plotting the calculated conductivity versus inverse temperature. Either type of analysis is only accurate when the resistance and capacitance of the relaxation processes being measured are both independent of frequency. A truly bulk response will always have constant R and C at a given temperature. This is not the case for space charge polarization under biasing conditions or diffusion controlled processes. In both of these cases, the number of mobile charge carriers will change the values of R and may also affect the value of C .

1) A Debye-type dielectric polarization process

Before describing a dielectric polarization with a parallel leakage current, it is useful to describe the Debye relaxation in more detail. As described in references (Cao and Gerhardt, 1990, Gerhardt, 1994) and others, the Debye relaxation process can be affected by the strength of the dielectric relaxation, referred to as the relaxation ratio r , which is equal to $\epsilon_s/\epsilon_\infty$. (Cao and Gerhardt, 1990). In Fig. 13, the effect of this relaxation ratio on the ability of the dielectric process to begin showing some measurable impedance is displayed for several r values.

In addition to the Debye equation presented in Eq. (7), it is also possible to represent the Debye relaxation in terms of equivalent circuits, where a series R_1C_2 circuit is in parallel with a starting C_1 where $r = C_2/C_1$ and the Debye relaxation time constant is equal

Fig. 12 (A) Schematic of a dielectric loss ($\tan \delta$) process at different temperatures. Loss peaks shift to higher frequency ($f_{\max}$) as the temperature is increased. (B) Plot of $f_{\max}$ versus the reciprocal temperature allows determination of the activation energy for the dielectric loss process.

Fig. 13 Effect of relaxation ratio (r) on the complex permittivity and frequency explicit real and imaginary permittivity (A) Complex permittivity semicircle increases in size when ϵ s increases (B) Real permittivity plotted vs. frequency show sigmoidal shaped curves accompanied by a peak in the imaginary permittivity function that increase in height as the value of r increases (C) As the relaxation ratio r increases, one can see the formation a more complete semicircle in the complex impedance graph.

to R_1C_2 . This is shown in Fig. 13A. As the value of the relaxation ratio increases from 2 up to 1000, one can detect the onset of the formation of a semicircle in the complex impedance plane and a peak in the imaginary impedance as displayed in Fig. 13B and D. It should be mentioned that dielectric loss peaks (similar to those shown in Fig. 13C) by themselves do not give rise to a long range conductivity process because the path is always dominated by the higher valued capacitor C_2 which results in a fastly increasing imaginary impedance as in Fig. 13B. This is also seen in Fig. 13D as well as part (d) in the graphical abstract where the complex impedance is shown on a log scale to demonstrate the effect of the bulk impedance of the sample (R_1) while keeping the relaxation ratio constant. The dielectric loss peak is seen to shift to lower frequencies as the bulk resistance of the sample increases.

2) A Debye process with a parallel leakage path

If we now add a parallel leakage path by adding an additional resistor R_2 as in Fig. 14, we can better observe the ability of a leakage path to dominate the spectra measured as it can convert to a simple conducting process governed by the parallel combination of R_2C_1 . This is shown in Fig. 14, where the no leakage Debye case with the same values of R_1 , C_1 and C_2 is also included for

Fig. 14 Comparison of the response of a material with a Debye relaxation process with and without a leakage path. (A) Real and imaginary permittivity vs. frequency showing that the real component does not change but that the imaginary component shows a huge difference. (B) The complex permittivity still shows a semicircle for the purely Debye case while the leakage case no longer shows a complex permittivity semicircle. (C) The leakage case is totally dominated by the leakage path whereas the purely Debye case shows a semicircle shunted by a straight line dominated by the low frequency capacitance (D) the real and imaginary impedance vs. frequency graphs do show the appearance of a relaxation for both cases but displayed graphs only clearly show the frequency dependence for the pure Debye case as the other curves are a lot smaller and cannot be detected using the scale shown. Modified from Gerhardt RA (2005) Impedance spectroscopy and mobility spectra. In: Bassani G, Liedl G, Wyder P (Eds.). *Encyclopedia of Condensed Matter Physics*. Elsevier Press, pp. 350–363.

comparison. Fig. 14A shows that both the regular Debye case with no leakage and the one with a leakage path overlap in the real part of the permittivity but the similarity ends there as in the imaginary permittivity, the presence of the leakage path results in a fastly increasing imaginary ϵ'' that completely swamps the dielectric peak that one can see for the Debye case with no leakage. This is also detectable in the complex permittivity graph in Fig. 14B, where complex permittivity shows the semicircle for the Debye process while it is no longer available for the case with a leakage path. It is easy to see that when a clearly defined impedance semicircle is observed due to the presence of the leakage path, we no longer can see a semicircle in the permittivity plane especially if the bulk resistance is large as shown in Fig. 14C, where the bulk resistance is 1 M Ω . Furthermore, the complex impedance responses for the case with the leakage can vary widely as shown in Fig. 14D. The effect of the leakage path can also be included in the regular Debye equation where the easiest way to represent this is to add a leakage current, σ , term as follows:

$$\epsilon^* = \epsilon_\infty + \{(\epsilon_s - \epsilon_\infty)/[1 + j\omega\tau]\} - j\sigma/\omega \quad (15)$$

The corresponding equivalent circuit will contain a series RC circuit in parallel with a leakage resistor, which is also in parallel with the bulk capacitance as described above.

3) A simple conducting process represented by a parallel RC circuit

To fully illustrate the case of a material or device with some measurable dc conductivity, the easiest model to use is the RC in parallel. Fig. 15 demonstrates how the four dielectric functions appear when we only have such a circuit. It is clear that both the impedance and electric modulus show a semicircle (in opposite quadrants), whereas the dielectric permittivity and the admittance do not show any frequency dependence. This is one of the reasons why for a long time, no one interested in measuring ionically conducting materials ever thought of looking at the permittivity as one could not find any interesting trends. See the section of parallel RC circuits in series for more details.

4) A simple conducting process represented by a parallel RL circuit

A similar situation is obtained for much more conducting or highly conducting semiconductors which can usually be represented by an RL in parallel. Fig. 16 displays the complex graphs for all of the dielectric functions. Only the complex impedance shows a semicircle in the 4th quadrant in this case while the admittance shows no frequency dependence. The electric modulus and the dielectric permittivity both show negative values for the real components. This should not be surprising since very conducting materials can also get polarized due to the presence of electron clouds (Kao, 2004). Many other conducting materials can also be represented by an RL circuit in series (Muhlbauer et al., 2014; Pruyn and Gerhardt, 2015; Bertram and Gerhardt, 2009) but they often contain additional circuit elements. Some additional information may be found in a recent article (Gerhardt, 2022) and its accompanying tutorial.

5) A solid state ionic material with different response at the grain boundaries than within the bulk grains

The simplest equivalent circuit to represent an ionically conducting material contains two parallel RC circuits in series, as was shown in Fig. 4. The physical meaning for each of the four options shown is quite different. Table 3 listed some of the possible physical processes that may be represented in each of these cases.

Irrespective of the source of the frequency dependence, when the difference between the relaxation times of the two processes present is small, i.e., less than one or two orders of magnitude, or either the R or C are very small or large, one of the processes may be overshadowed by the other in the impedance plane as was demonstrated in Fig. 4D. This is when multiplane analysis should be used, as different processes can be best displayed in different dielectric functions, according to their R/C and L values. To illustrate this point, Fig. 17 is presented below.

Fig. 4A–D displayed the complex impedance spectra for a bulk ionic conductor with $C_1 = 1$ pF, which has different electrical responses at the grain boundaries (with $C_2 = 1$ nF) depending on the ratio of the bulk resistance $R_1 = R_g$ and the effective resistance at the grain boundaries labeled $R_2 = R_{gb}$. (modified from Gerhardt, 2005). The following cases were included: (1) $R_g = R_{gb}$, (2) $R_g < R_{gb}$, (3) $R_g \ll R_{gb}$, (4) $R_g > R_{gb}$ and (5) $R_g \gg R_{gb}$. These figures illustrate that only looking at the complex impedance plane may prevent identification of the presence of a second process.

Taking the impedance graphs from Fig. 4D which correspond to cases 3 and 5 that do not provide any indication that a second process may be there and converting them to admittance, dielectric permittivity and electric modulus clearly reveals the existence of more than one process, one can obtain Fig. 17A–D for case 3. Furthermore, plotting the Bode plots also highlights the presence of two processes in some cases. The imaginary functions are generally dominated by the process with the largest value but it is easy to see that more than one process can be seen for impedance and electric modulus. As discussed in the earlier section, overlapping time constants have become a lot more common as the capacitances of nanophase materials ($\sim$ nF) have similar values to those of the grain boundary regions (also $\sim$ nF). This makes it more challenging to identify the different processes that may be present in a given nanomaterial. However, using logarithmic scales, as suggested by Jonscher (1983) may also reveal the presence of more than one process when the time constants are either too close together to be seen on a linear scale or the magnitude of one of the R/C and L components are too far apart. As stated before, one can always consider graphing them on a logarithmic scale if necessary. The videos shown in the supplementary illustrate how the difference in the time constants for each process can be used to detect the presence of more than one process but often it is necessary to transform the data into all four dielectric functions for a more complete assessment.

Fig. 15 Complex plots and Bode plots for a parallel RC circuit displaying all dielectric functions (Z^* , Y^* , M^* and ϵ^*) showing how the same equivalent circuit can appear totally different when looked at by converting to the other dielectric functions.

Fig. 16 Complex plots and Bode plots for a parallel RL circuit displaying all dielectric functions (Z^* , Y^* , M^* and ϵ^*) showing how the same equivalent circuit can appear totally different when looked at by converting to the other dielectric functions.

Fig. 17 Complex plots and Bode plots for two parallel RC circuits in series, where R_1 represents the bulk phase and has a much smaller resistance than the grain boundary phase in a semi-insulating material such as an ionic conductor. These graphs demonstrate that in this instance it is necessary to look at the frequency explicit plots to detect the presence of the second process. (A) Complex impedance same as Fig. 4D and its corresponding real and imaginary impedance. (B) Complex admittance and its corresponding real and imaginary admittance, (C) complex electric modulus and its corresponding real and imaginary electric modulus, (D) complex permittivity and its corresponding real and imaginary permittivity.

6) A semiconducting material with space charge polarization at the electrode/material interface

When making measurements of a semiconducting material, it is important to pay attention to whether the electrode contact is ohmic or not. If the electrode contact is non-ohmic or the charge transfer between the semiconductor and the electrode is inefficient, then an additional semicircle may be observed, which may be interpreted to be related to the space charge polarization at that interface. Fig. 18A and B present the simulation of the complex impedance and Bode plots of impedance graphs for a semiconductor in contact with a blocking electrode (Jamnik and Maier, 2001). Fig. 18A displays two curves. The semicircle closest to the origin coincides in both curves while the other semicircle does not. When the semicircles don't change, the response can be said to be representative of the bulk of the material (this needs to be confirmed by determining the geometric capacitance of the measured device). The Bode plots in Fig. 18B also highlight the difference between the two cases and can sometimes be used to confirm that one has more than one process occurring even if only one semicircle is visible. When electrode contact effects dominate, changing the size of the electrodes is one way to minimize the contact effects (Mebane and Gerhardt, 2006), changing the electrode material to get better matching with the surface potential of the material being electrode is another (Ou et al., 2003). Finally, if it is not possible to get a high quality ohmic contact, one can resort to superimposing a dc bias to decrease the Schottky barrier height (Bertram and Gerhardt, 2009), which will affect the barrier term but not the bulk term. The values of the circuit elements used for generating Fig. 18 were taken from an article by Mebane (Mebane and Gerhardt, 2006) where the size of the electrodes minimized the Schottky barrier error on the electrodes and thus resulted in a decrease in the size of the contact semicircle. This is also shown in one of the videos where the second semicircle (related to the electrode contact) decrease. Contact effects are quite common for semiconducting materials such as SiC (Huang et al., 2020) which usually forms Schottky barriers in contact with most metallic materials, but has recently been found to make good ohmic contact with Ni (He et al., 2019). Interestingly both types of contacts are desirable as certain applications may benefit from having a Schottky contact.

7) A highly conducting nanomaterial

For materials such as carbon nanotubes, graphene, indium tin oxide (ITO) or conducting polymers, it is not uncommon to observe a plethora of diverse responses as a function of the film thickness (Xia and Gerhardt, 2016; Sethuraman and Gerhardt, 2021), concentration of the active conducting species (Muhlbauer and Gerhardt, 2013; Jiang and Gerhardt, 2021; Sari et al., 2006) and details about the substrate characteristics (Xia et al., 2019; Sethuraman and Gerhardt, 2021). More details regarding conducting materials and their electrical response (Jonscher, 1983). The images presented in Fig. 6, where combinations of parallel RC and parallel RL circuits in series were presented, can all occur in these types of materials. The case for the RL time constant being less than the RC time constant will be discussed here as it has been observed the most when these materials are in transition from a semi-insulating condition to a more conducting condition (Muhlbauer et al., 2014; Muhlbauer and Gerhardt, 2021). As discussed in the previous section (3), truly conducting materials will give rise to an RL in series after transitioning from an RL in parallel.

Fig. 19A depicts the simulation of a complex impedance graph for a carbon nanotube film in the process of transitioning from a semi-insulating film to a more conducting film (Muhlbauer and Gerhardt, 2021). The model here has been simplified in order to match with the simpler combination of RC and RL components where the time constant for the RL portion is less than that for the RC portion that was shown in Fig. 6. Hence the parallel RL portion appears at the lowest frequencies and shows up in the 4th quadrant. This type of behavior is observed in many other nanomaterial conducting films and devices made with films with nanodimensions.

Fig. 19B displays the real and imaginary impedance where both the inductive and the capacitive portions can be detected. They are then transformed into the admittance graphs shown in Fig. 19C and D, the electric modulus graphs in Fig. 19E and F and Fig. 19G and H for the permittivity. It is easy to see that the admittance is fairly comparable to the inverse of the impedance, while the electric modulus is also showing the same trends as the inverse of the dielectric permittivity. The most important item to note is that one can detect the presence of a negative permittivity or negative capacitance in Fig. 19H. When the films are made to contain more layers, the material response becomes much more conductive and the equivalent circuit further simplifies to a series RL (Muhlbauer and Gerhardt, 2021; Gerhardt, 2022). The videos provided also include cases that combine parallel RC and parallel RL in series and demonstrate all arrangements displayed in Fig. 6.

8) Bulk response and interfacial responses of multiphase systems

Many of the nanomaterial films are essentially composite films which initially incorporate the properties of the underlying substrate (Muhlbauer et al., 2013; Kumar and Gerhardt, 2012) and then eventually result in a response which is only related to the film itself once it becomes thick enough. The situation is again different for the impedance response of a multiphase bulk material where one can expect at least two different frequency dependent regions, one related to the matrix or majority phase and the other to the filler or minority phase. A lot of work has been done to characterize the electrical properties of polymer composites (Watt and Gerhardt, 2020a; Watt and Gerhardt, 2020b; Capozzi et al., 2008; Sullivan et al., 2014) and ceramic composite materials (Bertram and Gerhardt, 2009; Runyan et al., 2001b; Rudzik and Gerhardt, 2020) where the matrix is generally insulating and the filler is usually conducting and the results are found to be quite dependent on the size, shape and distribution of the two phases and the formation of percolating paths (Runyan et al., 2001a; Gerhardt et al., 2001).

The two-layer condenser, first proposed by Maxwell and Wagner to represent a layered material, contains layers of a material with conductivity σ_1 and dielectric permittivity ϵ_1 that are placed with alternating layers of a material with conductivity σ_2 and

Fig. 18 Complex plots and Bode plots for two parallel RC circuits in series, where R_1 represents the electrical response of a bulk semiconductor phase and has a much smaller resistance than the blocking electrode. These graphs demonstrate that in this instance it is necessary to look at the frequency explicit plots to detect the presence of the second process. (A) Complex impedance same as Fig. 5A and its corresponding real and imaginary impedance, (B) Complex admittance and its corresponding real and imaginary admittance, (C) complex electric modulus and its corresponding real and imaginary electric modulus, (D) complex permittivity and its corresponding real and imaginary permittivity.

Fig. 19 Complex plots and Bode plots for a parallel RC circuit in series with a parallel RL circuit, where the resistance for the capacitive circuit is larger than the resistance for the inductive circuit. The RC circuit represents the behavior of the highly conducting nanomaterial film combined with the properties of the substrate while the inductive circuit displays the more conductive nature of the thin film nanomaterial. (A) Complex impedance (shown in Fig. 6) and its corresponding real and imaginary impedance displaying the capacitive circuit in the first quadrant and the inductive circuit in the 4th quadrant. (B) Complex admittance and its corresponding real and imaginary admittance the exact opposite as the impedance, (C) The complex electric modulus and its corresponding real and imaginary electric modulus display a partial semicircle shunted by a straight line which is also repeated for the complex permittivity and its corresponding real and imaginary permittivity displayed in (D). Major difference is seen in the real part of the permittivity where a negative dielectric permittivity is displayed.

Fig. 20 Impedance magnitude $|Z|$ and phase angle plotted vs. frequency for a series of insulator-conductor composites as a function of increasing conducting phase. $|Z|$ graph needs to be plotted on a log scale so all measured values can be easily seen because of the large changes in impedance value. The phase angle displays the changeover from a capacitive dominated response to an inductive dominated response when the conducting nanoparticles are fully connected.

dielectric permittivity ε_2 and thicknesses of d_1 and d_2 (Von Hippel, 1954). This gives rise to the Maxwell-Wagner dielectric relaxation equations given below:

$$\varepsilon'_{M-W} = (\varepsilon_\infty)^{M-W} \left\{ 1 + \left[\frac{k}{1 + \omega^2 \tau^2} \right] \right\} \quad (16)$$

where $k = [(\varepsilon_s)^{M-W} - (\varepsilon_\infty)^{M-W}] / (\varepsilon_\infty)^{M-W}$ and $\tau = [\varepsilon_1 d_2 + \varepsilon_2 d_1] / [\sigma_1 d_2 + \sigma_2 d_1]$ and

$$\varepsilon''_{M-W} = (\varepsilon_\infty)^{M-W} \left\{ \left[\frac{\tau}{\omega \tau_1 \tau_2} \right] + \left[\frac{k \omega \tau}{1 + \omega^2 \tau^2} \right] \right\} \quad (17)$$

It should go without saying that quite different spectra will be obtained depending on what the values of σ_1 , ε_1 , σ_2 , ε_2 are. The basic interpretation is that the response at the highest frequencies represents the “effective” response of the bulk of the material whereas the response at the lowest frequencies takes into account the interfaces between the two materials (Pruyn and Gerhardt, 2011). It should be added that it may be necessary to consider additional processes such as defect relaxation within the more insulating type material and/or additional space charge polarization processes at the interfaces of the more conducting material.

Because many insulating materials have resistivity $> 10^{12} \Omega\text{-cm}$ and conducting materials have resistivity less than $10^2 \Omega\text{-cm}$, this leads to the possibility of seeing a 10 order of magnitude change or more in the measured properties, especially around the composition region where percolation occurs (Runyan et al., 2001b; Gerhardt et al., 2001). The easiest way to deal with such an enormous change in properties is to plot the impedance magnitude and phase angle vs. frequency as was done in Fig. 1. The impedance magnitude will allow visualizing the huge changes in the resistivity (impedance) more easily than the complex plots, while the phase angle will allow identification of capacitive and inductive responses quickly because of the sign difference.

Fig. 20 demonstrates this for a series of ceramic composites consisting of an insulating matrix filled with conducting nanoparticles. The values used here were taken from a study where borosilicate glass filled with antimony doped tin oxide nanoparticles were fabricated and their impedance behavior was characterized (Pruyn and Gerhardt, 2015). This is one of the first instances where the properties of the individual phases were measured separately by compressing powders of the constituent phases and measured in situ (Pruyn and Gerhardt, 2011) and then those values were used to determine the expected response of the fabricated composite materials. The behavior observed in this figure is quite representative of the behavior of insulator-conductor composites consisting of any material type that can undergo large changes in their electrical response. The large changes can be caused by some compositional variation (Rudzik and Gerhardt, 2020), some polymer conformation (Alig et al., 2007), some type of atmosphere control during measurements (Dong and Gerhardt, 1998), annealing prior to measurements (Joshi and Gerhardt, 2013) or some fabrication variations that can change the arrangement of the precursor phases (Gupta et al., 2006; Ou et al., 2006a; Ou et al.,

2006b; Sullivan et al., 2016; Jin and Gerhardt, 2017; Watt and Gerhardt, 2020a). Characterizing the impedance properties of other materials such as hybrid organic-inorganic materials, metamaterials, biomaterials as well as superconductors as a function of composition, heat treatment or excitation with magnetic or optical signals would benefit from detailed studies. In fact the measurements could even be used to understand low temperature physics phenomena such as metal-superconductor transitions or insulator-superconductor transitions (Çavdar et al., 2011; Huang et al., 2022) to help the fields of spintronics, magnetoresistance and quantum devices.

Data analysis

Some guidelines have already been provided in the earlier sections, but some additional details will be given here. The most important concept is that of the geometric capacitance. The correct way to obtain the capacitance of a conducting process is to use the intercept of the impedance curve with the real axis to obtain, R , for that process (Gerhardt, 2005). To obtain the capacitance, the peak frequency must be identified (as was schematically shown in Fig. 2A) so that the following equation can be used:

$$C = 1/2\pi f_p R \quad (18)$$

Similarly, if one wishes to obtain the inductance of a conducting process represented by a parallel RL circuit as shown in Fig. 2B then we would locate the peak frequency and use the following equation

$$L = R/2\pi f_p \quad (19)$$

If one is interested in characterizing the bulk electrical properties of a given material or device, the measured capacitance/inductance should be on the same order of magnitude as that expected for the physical dimensions of the sample or device measured. This means that if such an analysis gives a capacitance/inductance that is not in agreement with the expected values, then the measured data is NOT related to the bulk of the material or the device and is most probably related to some type of space charge polarization mechanism (see equivalent circuit combinations in Table 5).

Table 6 lists the expected capacitances for materials with different dielectric constants and different thicknesses (Gerhardt, 2005). A detailed paper focused on the effect of the size of the electrodes and the thickness of the materials on capacitance and resistance was published in Kumar and Gerhardt (2012). Results revealed that changing the physical dimensions of the electrode contacts and thickness of the samples can change the value of the individual values of R and C while the time constant remains the same (Kumar and Gerhardt, 2012). Additional confirmation that a measured process is related to a bulk process can be obtained by varying the applied voltage or changing the size of the electrode contacts. The response for a bulk process should remain the same, irrespective of the values of the experimental parameters whereas space charge processes will show large changes as discussed in the section on the effect of space charge polarization at the electrode/material interface. Instead, if they scale with these variables, it may be possible to separate electrode contact effects from internal interface effects.

In cases where the impedance is so large that the intercept with the real axis is not available experimentally, the capacitance of the material will only be able to be obtained from either the real dielectric permittivity or the real electric modulus spectra. In most cases, the permittivity value is almost constant as a function of frequency (Cao and Gerhardt, 1990; Kumar and Gerhardt, 2012). The only time that a semicircle will appear in both the permittivity and the electric modulus is when there is a dipolar type relaxation present as was shown in the section describing a Debye relaxation with and without a leakage path (see Figs. 13 and 14).

Separating individual processes present in the bulk becomes a little bit more difficult. For example, separating dipolar relaxation from ionic conductivity in a good ionic conductor is not possible at temperatures where the ionic conductivity is high (Von Hippel, 1954) as demonstrated in Fig. 14. However, carrying out measurements at lower temperatures will suppress the ionic conductivity and allow detection of defect dipole relaxation (Nowick and Berry, 1972; Gerhardt et al., 1987). Likewise, if a material has a large fraction of electronic conductivity and only a small fraction of ionic conductivity, detecting the latter is almost impossible within a single set of experiments. In such cases, the usage of blocking electrodes and/or controlled atmospheres during the measurements should enhance or diminish a particular type of charge carrier (Etsell and Flengas, 1970; Dong and Gerhardt, 1998) that will aid in the data interpretation.

Electromagnetic simulation software

In recent years, a large number of commercially available software packages have become available. Many of the software packages come complete with electrostatics and electromagnetics modules. They are used mostly to model the performance of devices, but physical arrangements of structures (at various length scales) are also possible. Most commercially available simulation software is finite element based (FEA) or finite time difference based (FDTD). Some progress has been made on implementing these packages to help simulate impedance data at the microstructural level, but much more work needs to be done before they become commonplace. Several examples of numerical simulations applied to impedance measurements can be found in work by the author's research group (Kumar and Gerhardt, 2012; Jin and Gerhardt, 2014; Jin et al., 2016; Jin and Gerhardt, 2017). Additionally there are many additional COMSOL simulation proceedings papers that range from biomedical applications to antennas to resonators and beyond in the more than 2600 articles as of March 2022 located at <https://www.comsol.com/papers-presentations>. Simulations

1000	1×10^{-6}	4.43×10^{-07}
1000	1×10^{-9}	4.43×10^{-04}

directly related to impedance and dielectric spectroscopy as discussed here can also be found in papers by Kumar and Gerhardt (2009), Jin et al. (2016), Gerhardt and Jin (2015), Jin and Gerhardt (2017), Xia et al. (2019) and Jiang and Gerhardt (2021).

Recent advances (what to expect in the future)

Impedance spectroscopy of solid state materials continues to be used in a wide variety of fields and the number of applications continues to grow. Besides being useful as a way to determine the bulk electrical properties of materials and devices, it can also be used as a way to determine: (1) sensitivity and selectivity of gas sensors (Huang et al., 2014); (2) the degree of biocompatibility of new biomedical implants (Lau, 2017); (3) methods of quality control (Rath and Gerhardt, 2022; Titus et al., 2022); and (4) non-destructive characterization of materials used in electronics (Ramachandran et al., 2015), monitoring in structural applications (Ozer and Feng, 2020) and more.

More recent developments include magneto-impedance measurements (Tang, 2022), photostimulated-impedance measurements (Drisko et al., 2019) and bioimpedance measurements of tissue (Khalil et al., 2014). These new methods will be a great help to the burgeoning fields of spintronics, giant magnetoresistance, electro-optical devices and biomedical engineering. In addition, impedance measurements can be taken at all length scales and help detect different electric processes in materials, devices and structures. Localized measurements have been acquired using macro-, micro- and nano-sized electrodes for a number of years (Fleig and Maier, 1999; Kalinin and Bonnell, 2002; Descoteaux et al., 2020). However, simultaneous impedance and topographical data acquisition in an AFM/STM with different scanning probes has the potential to revolutionize the usage of impedance spectroscopy in the future (Kalinin et al., 2006; Rodriguez et al., 2006; Jesse et al., 2007; Balke et al., 2010; Gramse et al., 2014; Gruverman et al., 2019). Single frequency impedance amplitude and phase image scans have been collected using tapping mode or conductive AFM mode (Kalinin and Bonnell, 2002; Peng et al., 2008; Bertram and Gerhardt, 2009; Waddell et al., 2009; Xia and Gerhardt, 2016) and are being related to topographical images in order to understand what role different features play. The main challenge is that the smaller the probe is, the higher the impedance will be, making it difficult to acquire data as a function of frequency as the equipment specifications can be exceeded easily (Gerhardt, 2022). The band excitation mode of data acquisition (Jesse et al., 2007) is potentially one way to bypass that barrier but there are still some challenges. It is anticipated that with further developments in probe tips and measurement set ups as well as integration of multiple tools such as AFMs embedded in SEMs, AFM imaging in STEMs, nano-IR probes as well as continued testing of different measurement tools on the AFM, many more exciting experiments will be conducted.

Conclusion

Attempts to simplify the many facets of impedance spectroscopy have been made throughout this manuscript. The author has purposely excluded discussion of more complex equivalent circuits, as these only modify the basic concepts described here and more detailed examples can be found in the published literature for specific materials and devices. Instead, great effort was made to describe the importance of using all four dielectric functions to help derive understanding about the electrical processes being probed in solid state materials starting with the relationships between impedance and dielectric properties that have been the hallmark of the author's work (Cao and Gerhardt, 1990; Gerhardt, 1994). As such quite a few references from the author's own work were cited for additional context. For more short examples the reader is referred to a chapter by Bonanos et al. (2005) and three MRS conference proceedings books that the author was responsible for editing. These were published in print but are now all available on the MRS online proceedings by individual papers (Gerhardt et al., 1996; Gerhardt et al., 1998; Gerhardt et al., 2002).

Electrochemical impedance spectroscopy (EIS), which is mainly used to study corrosion of metallic materials (Scully et al., 1993), and is the basis for understanding electrical phenomena in the components of batteries, fuel cells and supercapacitors, was mostly excluded. There are excellent edited books and monographs (Lvovich, 2012; Scully et al., 1993; Orazem and Tribollet, 2017) that describe the use of liquid electrolytes that are necessary for many of these applications and others. It is also important to mention the two additional impedance edited books (Macdonald, 1987; Barsoukov and Macdonald, 2005) as well as the seminal work in dielectric spectroscopy by Von Hippel (1954) and Jonscher (1983, 1996) should be studied in more detail. Readers are urged to carefully review the extensive published literature in the subject matter of their own research interest, keeping in mind some of the guidelines presented here.

Multimedia

All videos provided for the online version of this article were generated by Yifan Jin and Rosario A. Gerhardt using a generalized equation method (Jin and Gerhardt, 2022). Videos 1–10 in the online version at <https://doi.org/10.1016/B978-0-323-90800-9.00021-4> include the effect of changing the time constant in all parallel RC and RL individual cases as well as the series combinations of the parallel RCs, RLs or RC and RL combinations.

Acknowledgments

The author is indebted to the Georgia Institute of Technology for giving her the opportunity to teach a full semester course every couple of years on the subject of impedance and dielectric spectroscopy for the last 30 years and to the many students who have taken her class and have contributed to her developing a better understanding of the subject matter. Additionally, the author would like to acknowledge the funding agencies that have supported her research work over the years (NSF, DOE, NASA), as well as to the many graduate students and collaborators she has interacted with. Finally, thanks to Goizueta Foundation Chair position for affording her the luxury of carving her own unique path in research.

Abstract

Plasmon-enhanced Raman spectroscopy (PERS), including surface-enhanced Raman spectroscopy (SERS) and tip-enhanced Raman spectroscopy (TERS), has experienced an incredible development over the past 20 years, thanks to its chemical selectivity, elevated sensitivity and spatial resolution well below the diffraction limit. These features have busted the application of PERS to many fields of science, such as material characterization, biochemistry, biomedicine and surface analysis. In this chapter, the basis of plasmonic enhancement are described, together with the main aspects related to the design and the fabrication of proper metallic nanostructures supporting localized surface plasmon resonance (LSPR). Finally, some relevant applications of PERS will be illustrated.”

Introduction

When a laser light illuminates a sample, the interaction between photons and matter can assume different forms (Demtröder, 2003). By considering, for instance, a molecular sample, photons can be simply transmitted through the sample, conserving their energy and momentum. Alternatively, if their energy matches the energy gap between two electronic or roto-vibrational levels of the molecules, photons can be absorbed, and, eventually, re-emitted as fluorescence. Finally, photons can be scattered elastically or inelastically. In elastic scattering, photon energy is conserved, so that the frequency ν , and therefore the wavelength λ , of the scattered light is equal to that of the incoming light. Depending by the size a of the scattering particle with respect to λ , elastic scattering is referred as Rayleigh ($a \ll \lambda$), Mie ($a \sim \lambda$) or geometric scattering ($a \gg \lambda$). In the inelastic scattering process, instead, photons energy is not conserved, and photons can either lose energy or gain energy from the interaction with scattering molecules (Vandenabeele, 2013). In a quantum picture, the energy exchange between incident photons and molecules occurring in scattering processes can be

[☆]Change History: February 2023. G Rusciano is involved in preparing the update. Updated queries and changed Figures 4, 6, 7, 11 and 12.

Fig. 1 Energy transfer process in Rayleigh (A), Stokes (B) and Anti-Stokes (C) Raman Scattering.

described in terms of the excitation of molecules from the ground state to a virtual state followed by a nearly simultaneous de-excitation toward a lower energy level (see Fig. 1). From the virtual state, most of molecules return back to the ground state through the emission of photons having the same energy as the incident photon (*Rayleigh scattering*). However, about 1 over 10^6 scattering processes follows a different path, involving a molecule decay from the virtual state toward an excited vibrational level (*Stokes scattering*). In this case, the photon energy is lower than that of the incident one and the energy defect ΔE is released to the internal (vibrational) energy of the molecule. The energy difference between the initial and final vibrational levels (Raman shift), expressed in wavenumbers $\tilde{\nu}(\text{cm}^{-1})$, is given through the relation:

$$\tilde{\nu} = \frac{1}{\lambda_{\text{inc}}} - \frac{1}{\lambda_{\text{scat}}} \quad (1)$$

in which λ_{inc} and λ_{scat} are the wavelengths of the incident and Raman scattered photons, respectively. As result, the photon red-shift due to Stokes scattering is intrinsically connected to the molecule energy diagram. Finally, molecules starting from an excited vibrational level can be excited to the virtual state and decay to the ground state (*anti-Stokes scattering*). This process produces photons with energy higher than that of the incoming photons: the energy defect is now transferred from molecules to photons. Since the number of molecules in an excited vibrational level decreases as $e^{-\Delta E/KT}$ (according to the Boltzmann statistic), anti-Stokes scattering is much less probable than Stokes scattering (typically by a factor around 1000). The spectral analysis of the inelastically scattered radiation is the subject of Raman spectroscopy (RS). Typically, Raman analysis is usually limited to the observation of the Stokes scattering (red-shifted photons), due to the higher cross-section with respect to anti-Stokes scattering.

From an experimental point of view, a Raman spectrum is typically obtained by dispersing the scattered photons by means of diffraction gratings and recording the so-dispersed radiation by means of a sensitive CCD camera. Since different molecules have bonds vibrating at well-defined frequencies, it turns out that the Raman spectrum consists of quite sharp peaks representing the actual *chemical fingerprint* of the molecule. This features clearly explains the wide diffusion of RS for the identification of analytes and the study of their evolution resulting from external stimuli or from the interaction with the environment. In particular, RS has revealed a powerful tool for the analysis of bio-systems, thanks to the relatively low Raman cross-section of water, which enables the observation of analytes in aqueous environment (Butler et al., 2016). The RS Achilles' heel is the low Raman cross section (of the order of $10^{-30} \text{ cm}^2/\text{mol}$), which makes it prone to be hidden by the contribution of other optical process, in particular fluorescence (cross section of the order $10^{-18} \text{ cm}^2/\text{mol}$). To overcome this issue, Raman scattering can be amplified by exploiting the enhancement of Raman cross-section which occurs when the frequency of the Raman probe is close to the frequency of an electronic transition. Such enhancement is typically in the $10^3 - 10^6$ range. This effect, which greatly improves the sensitivity of Raman spectroscopy, is referred as Resonance Raman scattering (RRS) (Demtröder, 2003; Efremov et al., 2008). RRS has been observed for several classes of biologically important molecules, such as metalloporphyrins and carotenoids, which have strong electronic transitions in the visible region, due to the presence of chromophors. In this condition, Raman scattering from the chromophoric moiety is greatly enhanced with respect to the contribution from the surrounding protein matrix. Raman signals intensity can be also increased by taking advantage from nonlinear effects which arise from induced polarization dependent by second and higher order electric field strength terms. Such terms, which become important for samples illuminated by high-power lasers (usually pulsed lasers) are at the basis of nonlinear Raman-based techniques (Hamaguchi, 2009; Harvey et al., 1981), including stimulated Raman scattering (SRS), hyper Raman (HR), coherent anti-Stokes Raman spectroscopy (CARS), coherent Stokes Raman spectroscopy (CSRS), stimulated Raman gain (SRG) and inverse Raman scattering (IRS). Such techniques can be advantageous when the quantum yield for the generation of fluorescence is particularly high so that fluorescence signal swamps the weak Raman signal.

A huge step forward to the diffusion of Raman spectroscopy in research laboratories is due to the lucky marriage of spectroscopy and plasmonic, which has generated Plasmon-Enhanced Raman Spectroscopy (PERS). The key event in this regard occurred in 1974 during Raman analysis of pyridine molecules on a rough silver electrodes by Fleischmann and co-workers (Fleischmann et al., 1974). The authors observed an anomalous enhancement of Raman signal from such molecules, which was initially ascribed to the accumulation of molecules on the electrode surface. The connection of Raman signal enhancement to enhanced fields arising from localized surface plasmons in nanostructured metals came only several years later, thanks to the contribution by several groups

(Albrecht and Creighton, 1977; Jeanmaire and Van Duyne, 1977), including the fundamental contribution by Moskovits (Moskovits, 1978). Nowadays we know that an enhancement (up to 14 orders of magnitudes) of the Raman signal can be observed when the analyte is close to proper nano-sized metallic particles (NPs). This phenomenon is called Surface-Enhanced Raman Scattering (SERS) and, since its discovery, its use as analytical technique has grown exponentially (Han et al., 2022; Langer et al., 2020).

As a matter of facts, as the SERS 50th birthday approaches, thousands of SERS-related papers have been published, which report the SERS theoretical basis (although still not fully understood), the design and fabrication of newly conceived enhancing substrates, and SERS application in several fields. Notably, thanks to the huge enhancement of SERS, the detection limit has reached the single molecule (SM) level. The remaining limitation of SERS, related to the diffraction-limited character of optical techniques, has been overcome by the fruitful combination of SERS analysis with scanning probe microscopy (SPM). The resulting technique is named Tip-Enhanced Raman Spectroscopy (TERS) (Pienpinijtham et al., 2022; Verma, 2017). In TERS, the near field scanning probe tip is covered with proper metallic NPs, so that it behaves as a sort of optical nano-antenna, giving place to huge amplification of the optical field as for SERS but only in proximity of the tip apex. In a sense, we can say that a nanosized SERS substrate is put *on-demand* to the desired position. Such approach has been first reported in 2000 by two almost simultaneous papers from the groups of R. Zenobi and S. Kawata (Hayazawa et al., 2000; Stöckle et al., 2000). Following these pioneer works, TERS is becoming a fundamental tool for nanoscale analysis and its range of application spans from bio-related investigations to the analysis of 2D materials and catalyzed chemical reactions. In this contribution, we first introduce the basic principles of plasmonic enhancement, by illustrating the case of a single NP and that of a plasmonic dimer. A special attention will be devoted for illustrating some fundamental approaches for the fabrication and the characterization of plasmonic nanostructures. Finally, we will illustrate some state-of-art applications of both SERS and TERS, with a special look to promising research trends.

Understanding PERS enhancement

It is widely accepted that the PERS enhancement can be attributed to two main enhancement mechanisms: electromagnetic and chemical enhancement. The Electromagnetic enhancement is generally the dominant contribution, providing a global enhancement factor up to 10^{11} . It is due to the coupling of the incident electromagnetic radiation field with the localized surface plasmons, which derive from the excitation of collective oscillations of electrons. Chemical enhancement originates from the interactions between the metal NP and the target molecule and contributes to the enhancement with a factor of the order of $10^2 - 10^3$. Formally, the Raman and PERS signals can be related by the relation:

$$P_{PERS} = G_{PERS} \cdot P_{Raman} = G_{EM} \cdot G_{Chem} \cdot P_{Raman} \quad (2)$$

being P_{SERS} and P_{Raman} the PERS and Raman signals, while G_{EM} and G_{Chem} are the electromagnetic and chemical gain factors. The origin of these two contributions is described below.

Electromagnetic enhancement

The interaction of metal nanoparticles with electromagnetic radiation is largely ruled by the metal free electrons in the nanostructure. To figure out the main features of such interaction, let us consider a metal NP irradiated by a laser beam. Driven by the external field, such electrons are forced to be displaced with respect to the positive ions of the crystal structure, globally leading to a dipolar charge distribution. In turn, the Coulombic attraction between the displaced electrons and the positive charges works against this displacement, acting as a restoring force. As result, under the combined action of both forces, free electrons in the nanostructure are forced to oscillate, in a fashion quite similar to the mechanical analog of the mass-spring oscillator. This collective oscillation of electrons, which is inherently localized into the NP structure, is referred as localized surface plasmon (LSP). Fig. 2A illustrates the LSP in the case of a spherical NP. As in the classical mass-spring system, a resonance effect can take place, if the forcing frequency is

Fig. 2 (A) Schematic illustration of collective electron oscillations in a spherical NP induced by an external electric field. (B) Sketch of the geometry describing the interaction of a molecular scatterer with a metal NP at distance d .

properly chosen. The LSP resonance (LSPR) gives rise to a strongly enhanced optical near-field, which is the key issue to explain the huge enhancement of the scattered field in PERS. It is not difficult to imagine that LSPR are strictly connected to NP size and shape. In the following, we will discuss the rising of such resonances starting from the simple case of a spherical nanoparticles with radius a much smaller than the incoming beam wavelength λ . Therefore, additional levels of complexity will be added, by relaxing the $a \ll \lambda$ hypothesis and considering nanoparticles with different shapes. Finally, we will consider the plasmonic dimer, the simplest system of interacting plasmonic NPs, which is the building block of all plasmonic nanoassemblies for SERS and TERS applications.

Plasmons supported by a nanosphere in the quasi-static approximation

In order to capture the essential features of LSPR, it is useful to consider the case of a metal NP interacting with an electromagnetic field in the so-called quasi-static approximation, which holds when $a \ll \lambda$, so that all the effects of retardation can be neglected. In this frame, all points in the NP respond simultaneously to the applied field, so that electric field is static around the particle. From a mathematical point of view, the Helmholtz equation for the potential Φ reduces to the easy-to-handle Laplace equation:

$$\nabla^2 \Phi = 0 \quad (3)$$

Finally, the electric field can be calculated from the relation:

$$\mathbf{E} = -\nabla \Phi \quad (4)$$

For the seek of simplicity, we can assume a static electric field $\mathbf{E}_0$ directed along the x-direction of a cartesian reference system, having the origin at the NP center. After a proper evaluation of the boundary condition for Φ on the NP surface, it can be shown that the electric field inside $\mathbf{E}_{in}$ and outside the NP $\mathbf{E}_{out}$ assume the form:

$$\mathbf{E}_{in}(\mathbf{r}) = \frac{3\epsilon_m}{\epsilon + 2\epsilon_m} \mathbf{E}_0 \quad (5)$$

$$\mathbf{E}_{out}(\mathbf{r}) = \mathbf{E}_0 + \frac{3\hat{\mathbf{r}}(\hat{\mathbf{r}} \cdot \mathbf{p}) - \mathbf{p}}{4\pi\epsilon_0\epsilon_m} \frac{1}{r^3} \quad (6)$$

being

$$\mathbf{p} = 4\pi\epsilon_0\epsilon_m a^3 \frac{\epsilon - \epsilon_m}{\epsilon + 2\epsilon_m} \mathbf{E}_0 \quad (7)$$

In Eq. (7), ϵ_0 is the vacuum permittivity, ϵ the complex dielectric constant of the NP and, finally, ϵ_m is the real dielectric constant of the (non-absorbing) material in which the NP lies. Notably, from Eq. (5), it is clear that the electric field inside the NP results to be homogeneous, a condition which can be sustained only if $a \ll \lambda$. Even more important, it is worth underling that the second term in Eq. (6) corresponds to field of a dipole located at the center of the NP and induced by the external field $\mathbf{E}_0$. According to Eq. (7), the polarizability assumes the form:

$$\alpha = 4\pi a^3 \frac{\epsilon - \epsilon_m}{\epsilon + 2\epsilon_m} \quad (8)$$

In general, the dielectric constant of a material is a complex, frequency dependent quantity $\epsilon = \epsilon' + i\epsilon''$. Intriguingly, both fields in Eqs. (5) and (6) are enhanced when the condition:

$$\epsilon + 2\epsilon_m \sim 0 \quad (9)$$

holds (Fröhlich condition). This resonance condition corresponds to the excitation of non-propagating surface plasmon, localized around the nanoparticle (LSPR). Clearly, the achievement of resonance depends from both NP and surrounding medium dielectric constants, which confers an intrinsic sensitivity to environment to all plasmon based approaches. Eq. (9) can be satisfied in the visible and NIR region by several metals (and, in particular, noble metals) which exhibit, in selected spectral ranges, a negative ϵ' and $\epsilon'' \sim 0$ (low losses), as illustrated in Fig. 3. For this reason, they are widely employed in LSPR applications. In particular, silver

Fig. 3 Real (A) and imaginary (B) part of the dielectric constants of selected metals in the 200–1200 nm spectral region. Adapted from ref. Pilot R, Signorini R, Durante C, Orian L, Bhamidipati M, and Fabris L (2019) *Biosensors* 9(2), 10.3390/bios9020057.

exhibits a quite broad plasmonic response covering both visible and NIR region. Similarly, gold is also very used, even if at wavelengths below ~ 500 nm, its plasmonic efficiency is affected by high interband losses. However, gold is sometimes preferred to silver due to its low reactivity to external agents. The plasmonic properties of metallic nanostructures are typically checked by measuring the extinction cross section σ_{ext} , which takes into account the contribution from both scattering and absorption cross sections ($\sigma_{ext} = \sigma_{sc} + \sigma_{abs}$). On the other hand, the scattering cross section can be obtained starting from the polarizability according to (Maier, 2007):

$$\sigma_{sc} = \frac{k^4}{6\pi} \cdot |\alpha|^2 = \frac{8\pi k^4}{3} a^6 \cdot \left| \frac{\varepsilon - \varepsilon_m}{\varepsilon + 2\varepsilon_m} \right|^2 \quad (10)$$

being $k = 2\pi/\lambda$ the wavevector modulus in the surrounding medium. Similarly, the absorption cross section is provided by the relation:

$$\sigma_{abs} = 4\pi k a^3 \cdot \text{Im} \left| \frac{\varepsilon - \varepsilon_m}{\varepsilon + 2\varepsilon_m} \right| \quad (11)$$

It is worth noticing that the resonance condition described by Eq. (9) holds for both absorption and scattering (and therefore also for extinction). However, σ_{abs} scales with a^3 whereas σ_{sc} scales with a^6 . As result, extinction is dominated by scattering for 'large' NPs, and by absorption for 'small' NPs.

Now, let us assume that a molecular scatterer is positioned at distance d from the NP (Fig. 2B). Starting from Eq. (6), it can be easily demonstrated that the ratio $A(v_L)$ between the moduli of the total E_{out} field and the incoming field E_0 scales according to:

$$A(v_L) \sim \frac{\varepsilon(v_L) - \varepsilon_m(v_L)}{\varepsilon(v_L) + 2\varepsilon_m(v_L)} \left(\frac{a}{a+d} \right)^3 \quad (12)$$

being v_L the frequency of the incoming beam. In Eq. (12) we have explicitly indicated the frequency dependence of the dielectric constants ε and ε_m . On the other hand, also the scattered beam at frequency v_s is enhanced, so that globally the plasmonic contribution G_{EM} to signal enhancement scales according to:

$$G_{EM} \sim \left| \frac{\varepsilon(v_L) - \varepsilon_m(v_L)}{\varepsilon(v_L) + 2\varepsilon_m(v_L)} \right|^2 \cdot \left| \frac{\varepsilon(v_s) - \varepsilon_m(v_s)}{\varepsilon(v_s) + 2\varepsilon_m(v_s)} \right|^2 \cdot \left(\frac{a}{a+d} \right)^{12} \quad (13)$$

Mie theory: Size and shape effects

A salient feature of Eq. (7) is that polarizability (and the resonance condition of Eq. (9) ruling scattering cross section) is independent from the NP size. This somewhat counter-intuitive outcome (a larger NP should radiate more) is clearly due to quasi-static approximation in which Eqs. (5) and (6) were obtained. A more general solution is provided by the Mie theory (Maier, 2007; Mulvaney, 1996), a full electrodynamic solution to the scattering problem. Within this theory, the extinction cross section can be obtained as a series of multipole oscillation according to (Maier, 2007, Mulvaney, 1996):

$$\sigma_{ext} = \frac{2\pi}{k^2} \sum_{n=1}^{\infty} (2n+1) \text{Re}(a_n + b_n) \quad (14)$$

In Eq. (14) a_n and b_n are the scattering coefficients, which are function of the NP radius a and the incoming beam wavelength λ and can be described in terms of the Ricatti-Bessel functions. In this frame, the effects of retardation, including radiative damping, are taken into account and the resonance condition for LSPR excitation is much more complex, showing explicitly a size-dependence. Fig. 4A illustrates this behavior for the case of Au—NP in water (Link and El-Sayed, 1999). Clearly, as the radius increases, LSPR resonances shift to the red and broaden, as consequence of the overlapping contribution from higher order multipolar excitation (Haynes and Van Duyne, 2001). Notably, in the case $a \ll \lambda$, only the first terms of Eq. (14) contributes significantly to σ_{ext} so that it assumes the simpler form:

$$\sigma_{ext} = \frac{24\pi^2 a^3 \varepsilon_m^{3/2}}{\lambda} \frac{\varepsilon''}{(\varepsilon' + 2\varepsilon_m)^2 + \varepsilon''^2} \quad (15)$$

and the resonance condition return to that obtained in the case of quasi-static approximation.

The Mie-based approach is quite effective also to describe the scattering from non-spherical NPs. As a general rule, when the NP geometry is distorted from that of a sphere, additional resonances appear for each axis of the asymmetric particle (Reguera et al., 2017; Sherry et al., 2006). Moreover, LSPR exhibits a dependence from the field polarization. For instance, in the case of gold nanorods, LSPRs split into two different modes: the longitudinal mode, which corresponds to free electrons oscillation along the major axes, and a transverse mode, due to oscillation perpendicular to the major axes (Tong et al., 2009). The first mode exhibits a red-shift as the nanorod aspect ratio increases, whereas the second mode undergoes a blue shift in the same condition.

Fig. 4 (A) UV-vis absorption spectra of 9, 22, 48, and 99 nm gold nanoparticles in water. All spectra are normalized at their absorption maxima, which are at 517, 521, 533, and 575 nm, respectively. Link S and El-Sayed MA (1999) *The Journal of Physical Chemistry B* 103(21): 4212. (B) Adapted from ref. Tong L, Wei Q, Wei A, and Cheng J-X (2009) *Photochemistry and Photobiology* 85(1): 21.

The plasmonic dimer

Single, isolated particles do not exhibit very large enhancement of the electromagnetic field, so that their practical utility in sensing platform is limited. Much higher enhancement can be achieved in the junction between two NPs (Fig. 5A). Such highly localized regions are usually referred as *hot spots* and are the basic structure of extended SERS substrates (Etchegoin and Le Ru, 2008). The essential features of the coupling mechanism among NPs can be enucleated by considering the simple case of two spherical NPs placed at distance d , usually referred as *plasmonic dimer*. In such system, coupling effect becomes important when d is decreased up to a distance comparable to the NP radius. It is possible to demonstrate that the plasmon resonance of such system can be described as result of the ‘hybridization’ of the elementary plasmons of the single NPs, as described in ref. (Deng et al., 2018). The hybrid modes of such system are depicted in Fig. 5. In particular, for an incoming beam polarization parallel to the dimer axis, the in-phase coupling forms a ‘bonding state’ with a red-shifted resonance, and the out-of-phase coupling represents an ‘antibonding state’ with a blue-shifted resonance.

Chemical enhancement

The chemical enhancement (CE) is a short-range effect that arises from the fact that molecule geometry and its electronic structure is affected by the interaction with the metallic surface. As result, the Raman cross-sections of a given vibrational mode can be, in general, different with respect to those of the free molecule. Accordingly, the CE is described by the relation:

Fig. 5 (A) Enhancement factor distribution in the region of the gap (2 nm) between two gold colloids (radii = 30 nm) calculated in the electrostatic approximation with finite-element modeling (for polarization along the vertical axis of the dimer). (B) Scheme of the plasmon hybridization model of a symmetric dimer, depicting in-phase/out-of-phase bonding/antibonding combinations of dipole moments. The arrows in the scheme indicate the dipole moments of the individual particles. (A) Reproduced from ref. Etchegoin PG and Le Ru EC (2008) *Physical Chemistry Chemical Physics* 10: 6079 with permission from the Royal Society of Chemistry. (B) Reprinted from ref. Deng T-S, Parker J, Yifat Y, Shepherd N, and Scherer NF (2018) *The Journal of Physical Chemistry C* 122(48): 27662.

$$G_{Chem} = \frac{\sigma_k^{ads}}{\sigma_k^{free}} \quad (16)$$

being σ_k^{ads} and σ_k^{free} the Raman cross-sections of the k^{th} vibrational mode of the adsorbed and of the free molecule, respectively. Although G_{PERS} is dominated by the electromagnetic contribution, chemical enhancement also plays a significant role, ruling the shape of PERS spectra in terms of both bands intensities ratios and Raman shifts. The strength of the perturbation induced on the molecule energy pattern depends by the kind of molecule-surface interaction. Physisorption (i.e. physical adsorption, driven by Van der Waals forces) gives rise only to a slightly modification of molecular structure. On the other hand, chemisorption (i.e. chemical adsorption, leading to the formation of a chemical bond between the molecule and the surface), induces a strong perturbation of the molecule energy diagram. Due to the variety and complexity of this scenario, although many relevant studies can be found in literature (Birke et al., 2010; Chen et al., 2010; Jensen et al., 2008; Kneipp, 2016; Mullin et al., 2012; Otto, 2005), a fully comprehensive theory to explain the CE has not been developed yet. Generally speaking, theoretical description of CE is usually performed by using a computational approach based on density functional theory (DFT) or by a modeling approach, in which only the features that are expected to play a role for the molecule-surface interaction are taken into account. In both cases, it is widely recognized that three different mechanisms contribute to CE:

- *Non-resonant chemical effect.* In this case, the molecular orbitals lay at energies far away from the Fermi level of the metal and the interaction between the molecule and the metal does not lead to the formation of new electronic states. Nevertheless, such interaction may induce an appreciable change of molecule polarizability, that is mirrored as a slight modification of the Raman shifts and of the intensities of the vibrational modes. Usually, DFT computational methods are used to evaluate the non-resonant chemical effect.
- *Resonant charge transfer chemical effect.* The interaction between the molecule and the metal leads to the creation of a new state, referred as charge transfer (CT) state. If the Raman probe energy is in resonance or pre-resonance with this state, some Raman modes can be strongly enhanced. In particular, Raman modes coupled to the allowed electronic transitions exhibit a quite relevant enhancement (resonant Raman enhancement). Typically, resonant enhancement is described by a computational approach.
- *Transient CT mechanism.* In this case, the chemical effect originates from a 'transient' charge transfer mechanism, based on a temporary electron transfer between the metal and the molecule. The description of the molecule-surface interaction by time-dependent evolution in the intermediate anionic state of the adsorbate is analogous to intramolecular Franck-Condon resonance Raman scattering.

Main PERS features

Plasmonic enhancement

As previously mentioned, the plasmonic amplification, defined by Eq. (2), can reach 14 orders of magnitude, allowing the detection of single molecules. From an experimental point of view, such amplification is evaluated by tacking into account the number of scatters contributing to both spontaneous (N_{spont}) and enhanced (N_{SERS} or N_{TERS}) Raman signals. In particular, in the case of SERS G_{SERS} is provided by the relation:

$$G_{SERS} = \frac{I_{SERS}/N_{SERS}}{I_{spont}/N_{spont}} \quad (17)$$

For a liquid sample, N_{spont} can be estimated starting from the relation $N_{spont} = cN_A \cdot V_{eff}$, where c is the sample molar concentration, N_A is the Avogadro number and V_{eff} is the effective excitation volume. On the other hand, N_{SERS} can be estimated from the surface density σ and the laser spot area A_{spot} according to $N_{SERS} = \sigma \cdot A_{spot}$. For TERS, the enhancement factor G_{TERS} can be estimated by the relation:

$$G_{TERS} = \left(\frac{I_{tip}}{I_0} - 1 \right) \frac{A_{spot}}{A_{NF}} \quad (18)$$

being I_{tip} and I_0 the Raman intensities obtained when the tip approaches to or is retracted from the sample, respectively, and A_{NF} is the near-field area (area explored by the tip). Typically, the enhancement produced by a single metallic colloidal particle (on a substrate or on the tip apex) is of the order of 10^3 , while much higher values can be obtained in the so-called 'hot-spots,' i.e. highly partially localized regions exhibiting giant field enhancement. As previously mentioned, the gap between the two NPs of a dimer is able to create such enhancing region. The role of such kind of hot-spots in plasmonic enhancement was accurately explored by Le Ru et al. (Le Ru et al., 2006), examining the field distribution in a dimer system, consisting in a couple of 30 nm silver NPs separated by a 2 nm. It was assumed that the dimer was excited by a laser beam with polarization parallel to the dimer axis. It was also assumed a uniform distribution of molecules on the surface of the two NPs. Clearly, an intense field region is created in the gap whereas only moderate field intensities can be experienced by molecules located elsewhere. In these conditions, it can be shown that the statistical distribution of probabilities to find a certain enhancement G_{EM} exhibits a typical long-tail behavior. Intriguingly, a single molecule

in a hot spot with a G_{EM} of 10^{10} provides the same Raman signal as 10^7 molecules experiencing a G_{EM} of 10^3 ! This simple estimation clearly highlights the necessity to fabricate plasmonic structures with a high hot-spots density.

Spatial resolution

A salient feature of plasmonic enhancement is its dependence from the distance between the metal nanostructure and the analyte. A rough estimation of such dependence is described in Eq. (13), obtained for the case of a scattering dipole in the quasi-static approximation, yielding to a d^{-12} dependence. This very short range character is somewhat mitigated in real systems. From an experimental point of view, such distance-dependence, which clearly rules the ultimate spatial resolution of plasmon-based techniques, was obtained in a SERS-based experiment by Masango et al. (Masango et al., 2016). In it, the authors used Al_2O_3 multilayers deposited by atomic layer deposition on a Ag substrate as 'spacers' between the probe molecules and substrate. In particular, the SERS from pyridine deposited on Al_2O_3 was acquired as function of the Al_2O_3 layer thickness (Fig. 6A). In this case, a d^{-10} distance dependence was observed, which also takes into account the number of molecules contributing to the signal (which scales as d^2). The dependence from distance was also investigated in a TERS experiment from Hartschuh et al. (Hartschuh et al., 2003). In this case, the authors measured the TERS signal from a single-walled carbon nanotubes (SWCN) as a function of the tip-SWCN gap. In this case, an inverse power law was observed, with the signal halved in ~ 10 nm.

SERS for sensitive analytes detection

As previously mentioned, the sensitivity of SERS can reach the SM level (Le Ru and Etchegoin, 2012; Le Ru et al., 2006). For this reason, SERS-based approaches are currently emerging as reliable techniques for analyte detection at low-concentration level (below nM range). At this purpose, two different approaches can be adopted (Pilot et al., 2019; Schlücker, 2014). The first, quite simple, relies on the direct detection of analytes, which are placed on proper SERS substrates (e.g. by analyte solution dipping or substrate immersion in the analyte solution). In this case, analyte presence and quantification is performed on the basis of the observation of the enhanced analyte spectrum. Such detection scheme is typically applied for analytes dissolved in pure water, but it becomes quite complicate for analytes in complex environments (such as biological matrices), in which the analytes spectral features can be masked by interfering species. In this case, indirect detection protocols can be applied, involving the use SERS labels (or tags), which are typically molecules exhibiting an high Raman cross-section (such as organic dyes), engineered to bind selectively to the analyte. In this case, analyte detection and quantification is performed on the basis of the SERS-tag spectrum. For SERS detection in complex matrices and at very low analyte concentration, separation and capturing techniques are also employed (Pilot et al., 2019). In particular, samples pretreatments by chromatographic approaches have been widely employed to separate (and also concentrate) analyte molecules. Immunoassays type approaches, tacking advantage of antibodies capability to selectively bind specific analytes (antigens), has been also applied as capturing tool for analyte detection (SERS immunoassay). They can be applied in both direct and indirect SERS detection approach. In the first case, the SERS substrate is functionalized with a specific antibody able to bind the analyte of interest, which is identified by its own spectral features, as well as by the changing of antibody spectral features due to binding to antigen molecules. Among indirect detection schemes, it is worth mentioning the approach illustrated in Fig. 7, for the detection of cancer biomarkers (Krasnoslobodtsev et al., 2015). It is based on the use of a gold capture surface (Fig. 7A) and an extrinsic Raman labels (ERL, Fig. 7B). Capture surface is prepared on a template stripped gold (TSG) substrate, successively modified with specific antibodies using thiolated linker molecules (DSP). ERLs are gold nanoparticles also modified with the same specific antibodies along with Raman reporter molecules (RRMs). The capture surface specifically binds and concentrates analytes from the

Fig. 6 SERS signal of the probe molecule as a function of the distance from the surface. A short and a long-range component are identified, associated with the morphological features of the silver substrate. The inset shows a SEM image of the substrate together with a simulation of the electric field. Reproduced from ref. Masango SS, Hackler RA, Large N, Henry A-I, McAnally MO, Schatz GC, Stair PC, and Van Duyne RP (2016) *Nano Letters* 16(7): 4251, PMID: 27243108.

Fig. 7 SERS-sandwich based immunoassay: (A) A gold capture substrate modified with linker molecules and antibodies. (B) Gold nanoparticles (ERLs) functionalized with Raman reporter molecules (RRM's) and specific antibodies. (C) Sandwich immunoassay where antibodies on the capture surface first bind antigens and subsequently bind ERL. (D) The sandwiched assay produces SERS readout with several characteristic bands from NBT Raman reporter molecules. The most prominent is $\nu(\text{NO}_2)$ - a symmetric nitro stretch at 1336 cm^{-1} . Adapted from ref. Krasnoslobodtsev AV, Torres MP, Kaur S, Vlasiouk IV, Lipert RJ, Jain M, Batra SK, and Lyubchenko YL (2015) *Nanomedicine: Nanotechnology, Biology and Medicine* 11(1): 167.

sample (Fig. 7C). Exposure of this substrate to a solution containing ERLs results in binding of an ERL to the capture surface via antibody-antigen interaction in a *sandwich* format (Fig. 7C). Sample analysis produces readout signal associated to the Raman reporter molecules (Fig. 7D). Similar approaches have been used for a sensitive and selective detection of relevant chemical biomolecules (Kunushpayeva et al., 2020; Porter et al., 2008).

Plasmonic nanostructures for SERS

Starting from the simple dimer structure described above, we can go on with complexity, by increasing the number of NPs involved in the plasmonic coupling, a process which leads to a more or less uniform system of interacting NPs, i.e. a SERS substrate (Stewart et al., 2008). Generally speaking, a reliable SERS substrate should exhibit a high density and uniform distribution of hot spots regions. Typically, for SM studies, the presence of intense hot-spots is highly desired, while uniformity is an indispensable feature for analytical applications. The variety of SERS substrates reported in recent years is enormous and obviously it is not possible to review the whole field herein. Nevertheless, SERS substrates can be grouped in three main categories: (i) metal NPs in suspension (ii) metal NPs immobilized on a (usually solid) support; (iii) nanostructures fabricated directly on bulk metal substrates. In the following, we brief review these approaches.

Suspension of metallic NPs

Spherical silver and gold NPs are among the widest employed SERS substrates for the analysis of systems in aqueous environment (Turkevich et al., 1953). Differently from the counterpart of immobilized NPs, they can be also injected (or spontaneously endocytized) into cells, acting therefore as plasmonic reporters from the inner cellular compartments (Dreaden et al., 2012; Lee and Meisel, 1982). Such NPs are typically produced by reduction of a precursor salt with sodium citrate in water. It is worth mentioning that silver NPs produced according to the recipe reported by Lee and Meisdler (Lee and Meisel, 1982) is one of the first substrates revealing an enhancing capability adequate for SM investigations and, after 30 years from its introduction, it continues to be used in a large variety of experiments. Plasmonic NPs can also be fabricated by laser ablation (Amendola and Meneghetti, 2009). In this case, a pulsed laser is focused on metal target placed in aqueous environment so that NPs generated by heating and photoablation of the target are directly transferred in the aqueous solution. The enhancing capability of colloidal systems can be easily exploited by inducing NPs aggregation, which creates numerous hot-spots in the interparticles regions. This can be achieved

by adding a salt (such as KCl and NaNO_3) to the solution. In such condition, the increase in the ionic strength of the solution reduces the screening of the charges at the NPs surface, inducing aggregation (Pamies et al., 2014). NPs aggregation in a confined region can be also achieved by using Optical Tweezers, which allow NPs trapping thanks to the gradient force generated by strongly focused laser beams (Foti et al., 2018). Notably, due to the complexity of aggregated NPs system, the plasmonic response can cover the whole visible-NIR spectral region.

Metal NPs immobilized on a support

A wide employed approach for the fabrication of SERS substrates relies on the assembly of pre-formed NPs (or NPs precursors) on a solid support. Recently, relatively ordered NPs arrays have been also deposited on flexible substrates such as paper or polymeric fibers (T. Vicente et al., 2018). An efficient approach for the production of an array of closely spaced, but physically separated, objects with optimal SERS properties was reported by the group of M.J. Natan (Freeman et al., 1995; Grabar et al., 1996). Briefly, a glass surface, silanized with (3-Aminopropyl)trimethoxysilane (APTMS), was immersed in an aqueous suspension of silver or gold NPs. Thanks to the strong interaction between the APTMS- NH_2 groups (exposed to the liquid phase), NPs self-assemble on the surface. In this way, the NPs spontaneous coalescence, occurring in the simple NPs solution drop casting on the surface, is prevented. By this approach, large area SERS surfaces (in the order of cm^2) can be produced, with good enhancement and reproducibility. Quasispherical gold NPs arranged on a APTMS- functionalized glass surface were also obtained by Lee et al. (Lee et al., 2017). In this case, a solution containing HAuCl , polyvinylpyrrolidone (PVP) and ethylene glycol were deposited on the surface, after which the Au-salt photoreduction was carried out by exposing the sample to a strongly focused femtosecond laser. In this way, SERS active surface are easily achieved by direct laser writing, which allows the production of the desired pattern with a spatial resolution in the micron range. Dense and ordered SERS nanopatterns can be obtained tacking advantage of the self-assembly of block copolymer (BCP) (Cho et al., 2012; Zito et al., 2015). The BCPs are macro-molecules composed of different types of polymer chains linked one to another with a covalent bond. Under certain conditions, BCPs tend to self-organize into aggregates of diverse morphologies such as spheres, cylinders or lamellae (see Fig. 8). Therefore, by chemically loading such aggregates with metal NPs, controlled NPs distributions can be obtained. Electrochemical techniques, including electrochemical roughening (ER) and the electrochemical deposition (ED), are also reliable methods for NPs deposition (Figueroa-Sobrinho et al., 2016; Fleischmann et al., 1974; Pilot et al., 2019). In ER, a short positive pulse is applied to a metal electrode, followed by a second pulse at a more negative potential. In this way, the first pulse causes the dissolution of small amount of metal from the initially smooth surface, while the second pulse induces the redeposit of the metal back onto the electrode. In ED, a proper application of electrical potential allows the deposit and adhesion of ions of the deposition material in the electrolyte to one of the electrodes. Usually, apart the metal salt to be deposited, an inert supporting electrolyte is added for sustaining and buffering the ionic conductivity, as well as proper ligands for controlling NPs shape and sizes.

Fig. 8 Steps involved for the fabrication of plasmonic template by BCP self-assembly, as described in ref. (Zito et al., 2015). The experimental approach is based on the self-assembling of PolyStyrene-*block*-Poly-4-VinylPyridine (PS-*b*-P4VP) micelles loaded with silver Ag-NPs. Briefly, micelle were prepared by tacking advantage of the hydrophobic character of PS and the hydrophilic character of P4VP, which is not soluble in non-polar solvents. Micelles were spined on a glass coverslip by spin coating. This procedure leads to the formation of a single micelles layer. Subsequently, the polymer is removed by UV radiation that induces the photo-fragmentation and subsequent evaporation of the polymer, thus leaving only the nano-cluster of silver NPs.

Nanostructures fabricated directly on bulk metal substrates

A wide class of techniques for SERS substrates fabrication can be classified as top-down approaches, involving the creation of nanostructures directly on a bulk metallic support by various lithographic techniques (Kahl et al., 1998; Kanipe et al., 2016; Zhu et al., 2011), such as electron lithography (EBL) (Kahl et al., 1998; Romanato et al., 2011), interference lithography (IL) (Lu and Lipson, 2010) and soft-lithography (SL) (Qin et al., 2010). EBL allows the production of substrates theoretically engineered to optimize the enhancement, in a tens of nm. EBL is based on the use of an electron sensitive polymer (the resist) on which the desired nanopattern is 'written' by an electron beam. This latter locally modifies the resist solubility rendering it more (positive resist) or less soluble (negative resist). After that, the resist is immersed in a proper solvent which removes the soluble portion of the resist. In this way a mask is created, which can be used to create the metallic pattern on a bulk metal surface. For instance, reactive ion etching (RIE) can be used to etch the surface parts not covered by the resist mask, or the metal can be deposited straight on the surface, followed by removal of the polymer (lift-off). EBL approach is very expensive and also time-consuming, so that it is not suitable for fabricating large area substrates. In IL, the mask is designed on a photoresponsive polymer, exposed to the periodically modulated path created by two interfering laser beams. Then, the process follows the same steps as in EBL. Clearly, the mask preparation phase is much easier with respect to EBL, but only periodic structures can be created, with a gap which is to approximately half of the wavelength of the radiation used. Soft lithographic methods allow the fabrication of large area substrates (up to $\sim 1 \text{ cm}^2$) (Rogers and Nuzzo, 2005), with good SERS performances, in a cheaper and more easily accessible way with respect to traditional lithographic methods, like photolithography and EBL. In the last years, solid-state dewetting (SSD) of thin (initially smooth) films has emerged as an easy tool for the production of SERS substrates (Capaccio et al., 2021; Kang et al., 2015). In SSD, a metallic layer deposited on a substrate by physical vapor deposition or sputtering. Such layer is in an unstable or metastable state because of the relatively high energies of the metal surface at the film-substrate interface. This no-equilibrium condition leads the metal layer to break up and agglomerate in nano-islands (dewet) following the application of a proper perturbation (such as a cold plasma), even at temperatures well below the metal's melting point.

TERS: Hot Spot On Demand

Many problems at the frontiers of materials science and biotechnology require a spatial resolution that is well below the diffraction-limited regime of conventional optical techniques. TERS offers the opportunity to fulfill this request (Cao and Sun, 2022; Deckert-Gaudig et al., 2017; Kumar et al., 2015; Pienpinijtham et al., 2022; Schultz et al., 2020; Shao and Zenobi, 2019; Verma, 2017; Zhang et al., 2016). As anticipated in a former paragraph, TERS relies on the combination of near-field scanning probe microscopy and enhanced Raman spectroscopy. In TERS, in fact, the metal (or metallized) near field scanning probe behaves as a sort of optical nano-antenna, that gives place to huge amplification of the optical field as for SERS but only in proximity of the tip apex (Fig. 9). Therefore, due the short-range character of plasmon resonance, the enhanced Raman signal can be acquired with a spatial resolution which is only limited by the tip geometry. Since the radius of curvature of scanning probe tips can be very small (of the order of a few nm), the obtained spatial resolution is well below the light diffraction limit and scattering can be excited in a nano-sized region, selected 'on demand' by the SPM system.

Moreover, TERS acquires simultaneously the topographic structure of the scanned surface. TERS can be combined with both Scanning Tunnelling Microscopy (STM) and Atomic Force Microscopy (AFM). In this latter case, the AFM probe is rendered active from the plasmonic point of view by decoration with a proper metallic nanotexture, following experimental approaches similar to that employed for SERS substrate fabrication. Historically, the first TERS realization dates back to 2000 by Kawata and co-workers

Fig. 9 Basic principle of TERS, combining the chemical sensitivity of SERS and the high lateral resolution of SPM.

Fig. 10 Common illumination and detection geometries for TERS. (A) Bottom-illumination. (B) Side-illumination. (C) Top-illumination.

(Hayazawa et al., 2000), shortly followed by Zenobi's group (Stöckle et al., 2000). These pioneering studies have well elucidated the main TERS features: a very high sensitivity (due to the near-field plasmonic enhancement) combined with an elevated spatial resolution, obtained by the scanning probe-based approach. Both these characteristics make TERS a unique tool, for instance, to directly localize and identify proteins and their conformation in a complex (e.g., native) environment. In addition, it represents an excellent tool for detecting biomolecules that are adsorbed, layered, or assembled on a large variety of surfaces and interfaces. There are three main TERS illumination and collection setups (Gao et al., 2018), referred as *bottom*, *side*, and *top* configurations, which are illustrated in Fig. 10. The main difference among them is the position of the microscope objective relative to the sample. In the case of the bottom illumination and collection (Fig. 10A), a radially polarized beam is used to illuminate the gap between the tip and the sample. The use of a radial polarization is used for both increasing the beam focalization and to produce a stronger longitudinal electric field along the tip axes. The disadvantage of this setup is that only transparent samples can be measured. By using the side illumination and collection configuration (Fig. 10B), non transparent samples can be also examined. In this case, a long working distance objective is used to focus the light on the tip. Clearly, in this configuration, the focal point is widened due to the angle of the lighting beam, which leads to a larger far field contribution. Finally, in top illumination and collection configuration (Fig. 10C), the laser illuminates the sample perpendicular to the surface. However, tilted tips have to be used to avoid shadow effects. For thin samples, the *gap-mode* configuration can be used (Wang et al., 2020). In it, the sample is placed on a flat metallic substrate (e.g. a gold substrate) and the plasmonic field is created in the gap between the tip and the substrate. In general, the tip can be also relatively smooth, being the plasmonic ruled by the tip-substrate gap. This configuration is ideally suited for SM investigations.

TERS probes nanofabrication and preservation

TERS probes are usually made by silver or gold. Au-probes present a longer lifetime but are less enhancing than Ag-probes. STM-TERS tips are typically obtained by electrochemical etching process (Lopes et al., 2013). Even though the plasmonic performances can significantly vary from one tip to the other, such easy and cheap approach makes the trade-off acceptable for most cases. For this reason, most of the research on TERS tip fabrication is focused on AFM-TERS tips. The most employed approach for the fabrication of such tips relies on the deposition of a silver/gold film on commercial AFM probes. Silicon probes and nitride probes are typically used, with the first type preferred due to the redshift of resonances as the refractive index of the material increases. By selecting accurately the process parameters (metallic layer thickness, deposition time, etc.), a granular metallic structure can be achieved, providing a dipolar excitation at the tip apex. Depending by the grains size and their peculiar arrangement near the tip apex, active TERS probe in the visible and NIR region can be achieved. Silver grains on a SiO_2 ($n = 1.5$) surface exhibit a resonance which is blue shifted with respect to that deposited on a Si surface ($n = 4$), so that for TERS analysis in the blue-green region, AFM Si tips are often oxidized by thermal annealing. Fig. 11A reports a TERS tip obtained by the group of Kawata, in which a 60 nm film was evaporated on a SiO_2 tip (Hayazawa et al., 2012). In this case, a clear granular pattern was obtained. A smoother metal film is instead obtained in the case of metal deposition by sputtering. As result, the plasmon activity of such tips is reduced, and their use is limited by the gap-mode configuration. Recently, Capaccio et al. reported an experimental procedure to strongly increase the roughness of Ag-sputtered probes by solid-state dewetting. The resulting tips exhibit a coral-like nanopattern (shown in Fig. 11C) and quite wide spectral response (Capaccio et al., 2020). Clearly, both evaporation and sputtering leads to a random distribution of NPs at the tip apex and, therefore, to a quite variable plasmon response. To fix this issue, numerous approaches have been reported to precisely attach a single properly designed NP to the tip apex. To this category it is worth mentioning the NPs positioning at the apex of an AFM probe by dielectrophoretic (DEF) forces reported in ref. (Leiterer et al., 2015) or the picking-up of gold NPs by using an AFM tip pre-coated with a glue, reported in ref. (Okamoto and Yamaguchi, 1997). Self-assembling of block-copolymers was also used to get a uniform distribution of NPs on a commercial AFM-tips, following an experimental approach similar to that used to produce hyper-uniform SERS substrates (Zito et al., 2016). Focused Ion Beam (FIB) based approaches were reported for the fabrication of TERS probes (Maouli et al., 2015; Umakoshi et al., 2016). Fig. 11 reports an AFM

Fig. 11 SEM images of TERS probes obtained by thermal evaporation (A) (Hayazawa et al., 2012), solid-state dewetting (B) (Capaccio et al., 2020), NPs attachment by DEF (C) (Leiterer et al., 2015), FIB (D) (Umakoshi et al., 2016).

cantilever on which a grating structure was patterned by FIB (Umakoshi et al., 2016). Such structure allows propagation of surface plasmon polariton along the tip axis and emission at the tip apex. In such a way, remote excitation becomes possible, leading to a consistent reduction of the far-field background. Clearly, FIB-based approaches are quite expensive and time consuming, so that it is not applicable for the production of a large number of tips.

A significant issue in TERS analysis relies on tip preservation for environmental contamination. This issue is particularly important for the analysis in liquid environment, where the attachment of molecules present in solution to the tip apex (or the tip edge) can significantly deteriorate the acquired signal. Moreover, detachment of the metal NPs from the tip can also occur, which leads to tip loss. More importantly, even in TERS measurements in air (and probe storage in air) suffer from degradation, although to a lesser extent. For this reason, storage in N_2 is recommended (Deckert-Gaudig et al., 2017). Appropriate coating with a robust and inert layer can significantly extend tips lifetime. This is the case of SiO_2 and Al_2O_3 (Deckert-Gaudig et al., 2017) layer. However, such coatings leads to a plasmon resonance shift and to some reduction of the plasmonic enhancement.

Overview of selected PERS applications and conclusion

SERS analysis has been performed on a large variety of molecules (including dyes) and macromolecules, especially for biomedical applications. It is possible to find in literature excellent reviews reporting a wide overview of SERS based applications (Han et al., 2022; Langer et al., 2020; Schlücker, 2014) that cannot be fully discussed in the following. DNA/RNA and their sequences are among the most investigated samples. As a matter of facts, detection of DNA sequences has clear applications for the detection and identification pathogens and early cancer detection. For instance, direct detection of RNA extracted from urine samples has revealed a reliable tool to detect prostate cancer with high specificity and accuracy (Sivanesan et al., 2014). More frequently, DNA is revealed by using an indirect detection approach (Ngo et al., 2013; Wabuyele and Vo-Dinh, 2005; Wang et al., 2017). A protocol for miRNA

detection, combining microfluidic with SERS and fluorescence analysis, has been developed by Wang et al, based on the development of a *molecular beacon* targeting miRNA (Wang et al., 2017). Such approach holds promise for the investigation of miRNA-related diseases. A particular miRNA, miR-21, was detected by a SERS sandwich-based approach by Guven et al. (Guven et al., 2014). Such miRNA constitutes an important biomarker, being over-expressed in several cancers. The author demonstrate a sensitivity for miR-21 detection under the nM level. In addition to DNA/RNA samples, a SERS sandwich-like approach was also used to detect relevant protein-based samples. This is the case of the approach developed by Wang et al. (Wang et al., 2011) to detect a pancreatic cancer biomarker, MUC4. In particular, SERS signals from gold nanoparticles functionalized with MUC4 antibody have proved to be an effective diagnostic tool for the detection of MUC4 from serum samples of patients. PSA, a wellknown prostate cancer biomarker, was instead detected by using Au-NPs functionalized with aptamers specific for detecting PSA. The developed protocol revealed a limit of detection at 5 pg/mL (Yoon et al., 2010). SERS analysis has been used to analyze cells and selected cellular compartments. Clearly, the most obvious compartment to be analyzed is the cellular membrane. As a matter of facts, by placing the cell on a solid SERS substrate, the only cellular compartment that ‘feels’ the plasmonic enhancement is that in contact with the substrate, i.e. the cytoplasmatic membrane (Zito et al., 2015). Such approach has been used to investigate the over-expression of carbonic anhydrase IX (CAIX) protein in SKOV3 cells (Rusciano et al., 2019). This protein is typically over-expressed in cells undergoing malignant transformations, so that such analysis can be used as a sensitive approach for early cancer detection. For the investigation of internal compartment, silver or gold colloids are used as SERS substrate, with the latter preferred due to their higher biocompatibility. Targeting to the selected compartment can be performed, to a certain extent, by a proper selection of NPs size and functionalization. Such approach has been used for the analysis of the endosomal system in eukaryotic cells (Kneipp et al., 2006). In this case, ~50 nm Au-NPs, endocytosed by cells, provided information of the nanoenvironment explored by cells, including the local pH value. Cancer cells obtained from biopsies were also investigated using colloidal NPs (González-Solís et al., 2013), which allowed the identification of chemical constituents, like phenylalanine, tyrosine, and tryptophan, and DNA bases. Particularly interesting is the use of SERS for the detection and identification of microorganisms such as bacteria, spores and viruses (Efrima and Bronk, 1998; Isticato et al., 2013; Kearns et al., 2017; Mosier-Boss, 2017; Wang et al., 2010; Witkowska et al., 2018), often even at strain level (Witkowska et al., 2018). For instance, it has been demonstrated that SERS spectra obtained by using Ag-nanorods arrays as SERS substrates, allow identification of strain of respiratory viruses, using extremely small samples amount (Shanmukh et al., 2006). A silver substrate, coated with antibiotics, was instead used by Waluk for detection of pathogenic bacteria, such as *Escherichia coli*, *Salmonella enterica*, and *Staphylococcus epidermidis* from blood samples (Sivanesan et al., 2014). The outcome of this study holds for the diagnosis of diseases related to clinically relevant pathogens.

As for SERS, TERS analysis spans over a wide variety of samples, including molecules, nanomaterial and 2D-materials. Interested readers are invited to refer to the many excellent reviews that can be find in literature (Deckert-Gaudig et al., 2017; Kumar et al., 2015; Pienpinijtham et al., 2022; Schultz et al., 2020; Shao and Zenobi, 2019; Verma, 2017; Zhang et al., 2016). Among bio-related samples, RNA and DNA have been widely investigated by TERS (Bailo and Deckert, 2008; Hennemann et al., 2010; Treffer et al., 2011). In particular, it was demonstrated the possibility to identify the contribution to the TERS signal of single bases when moving stepwise along single strands (Bailo and Deckert, 2008). Moreover, the investigation of hydrogen bonding between adenine and thymine is possible (Domke et al., 2007). These studies hold promise for the future identification of defects and local bonding in DNA strands. CNTs, and in particular single walled nanotubes (SWNT), are among the most employed samples (Hartschuh et al., 2003). This is mainly due the quite high Raman scattering cross section of SWNT, which allows the reduction of the TERS signal integration time and of the sample drift effects which deteriorates the simultaneously acquired topographic image. From the spectroscopic point of view, the observation of the G-band (graphitic-like mode at $\sim 1580\text{ cm}^{-1}$) and the D-band (defect-related band at $\sim 1350\text{ cm}^{-1}$) provide information on the purity and the presence of the defects in the tube. At the same time, the low frequency radial breathing mode can be used to estimate the CNT radius. Intriguingly, from the observation of the spectral shift of G-band along a CNT, it is possible to reconstruct the local stress field of the tube, due to the tube bending. It is clear that such shift is completely hidden by diffraction limited spontaneous Raman analysis (Hartschuh et al., 2005). Notably, in 2014 Chen et al. (Chen et al., 2014) have obtained the simultaneous chemical and structural analysis of individual carbon nanotubes (CNTs) by STM-TERS with 1.7 nm spatial resolution at ambient condition. Such impressive resolution can be improved when working with a low-temperature ultrahigh-vacuum scanning tunnelling microscope, reaching 0.7 nm (Liao et al., 2016). In 2019, a resolution at angstrom level has been demonstrated in UHV at cryogenic temperature by Zhang et al. (Zhang et al., 2019). In particular, the authors the possibility to get full Raman images of individual vibrational modes at the angstrom level for a single Mg-porphine molecule, revealing distinct characteristics of each vibrational mode in real space (see Fig. 12). Another field of application of TERS relies on the monitoring of chemical reaction. To the best of our knowledge, this issue was accomplished for the first time by Lantman et al. (van Schrojenstein Lantman et al., 2012), who investigated the dimerization of p-nitrothiophenol (p-NTP) adsorbed flat on a gold substrate by gap-mode AFM-TERS. In particular, dimerization was induced by a laser at 532 nm, while TERS signal was acquired by excitation at 633 nm. The possibility to monitor surface reaction by chemical interrogation of individual atomic adsorbates on a surface was instead demonstrated in ref. (Li et al., 2022). In particular, it is shown that single oxygen adatoms on a boron monolayer can be identified and mapped via ultrahigh vacuum STM-TERS with $\sim 0.48\text{ nm}$ spatial resolution and single bond (B-O) sensitivity.

An emerging area of TERS is surely the nanoscale analysis of biological interfaces, including the membranes of bacteria, viruses and spores (Ashton et al., 2011; Neugebauer et al., 2006, 2007; Olschewski et al., 2015; Rusciano et al., 2014), as well as biofilms. In this case, AFM-TERS analysis is performed, which typically provides a lower resolution, but is much more versatile, allowing investigation also in aqueous environment. Clear, operation in such environment adds an additional level of difficulty, due to the

Fig. 12 Angstrom-resolved Raman images of distinct vibrational modes for a single molecule by scanning Raman picoscopy. (A) Schematic diagram of SRP technique. The nanocavity defined by the silver tip and substrate generates a strong and highly confined plasmonic field, which is used for the excitation and emission enhancement of the Raman signals from a single molecule. (B) Typical Raman spectra acquired at representative positions labeled in (A): lobe (red), gap (green) and center (blue). (C) SRP spatial mapping images corresponding to the peaks labeled in (B), revealing different spatial distribution patterns for different Raman modes. (D) SRP image at 3072 cm^{-1} used for the estimation of spatial resolution. (E) Line profile of Raman signal intensities corresponding to the dashed line in (D), exhibiting a lateral spatial resolution down to 0.15 nm. Adapted from ref. Zhang L, Yang B, Ghafoor A, Zhang Y, Zhang Y-F, Wang R-P, Yang J-L, Luo Y, Dong Z-C, and Hou JG (2019) *National Science Review* 6: 1169.

much faster tip contamination and degradation. Typically, protective layer on the tips reduce this problem, as demonstrated for the analysis of calcium alginate fibers (Hayazawa et al., 2012). Moreover, the necessity to handle with complex spectra, multivariate approaches (such as Principal Component Analysis, PCA) can help to pick-up relevant information. This approach was demonstrated in ref. (Rusciano et al., 2014), in which PCA was successfully applied for the analysis of spores surface.

Abstract

Optical Tweezers, as the name suggest, are a tool to grab and hold an object using the light, that is without mechanical contact. The possibility for the manipulation of many different samples using only the light from a laser beam opened the way to a variety of experiments. Optical Tweezers, are nowadays employed in a multitude of applications demonstrating its relevance. Since the pioneering work of Arthur Ashkin, where he used a single strongly focused laser beam, ever more complex experimental set-ups are required in order to perform novel and challenging experiments. Here we provide a comprehensive discussion of the theoretical background and experimental techniques. We start by giving an overview of the theory of optical forces: first, we consider optical forces in approximated regimes when the particles are much larger (ray optics) or much smaller (dipole approximation) than the light wavelength; then, we, briefly, discuss the full electromagnetic theory of optical forces with a focus on T-matrix methods. Then, we describe the important aspect of Brownian motion in optical traps and how they are calibrated. Finally, we provide a review of some of the many experiments considering the perspective for future research.

Introduction

Evidences that the light can exert a force on matter are known since Johannes Kepler described the origin of comet tails as a consequence of the rays of the sun in 1619 (Kepler, 1619). After Maxwell's theory of electromagnetism in the late 19th century it was possible to describe the radiation pressure of light along the direction of its propagation (Poynting, 1884). Later, some experiments to detect the mechanical effects of light were performed (Nichols and Hull, 1901; Lebedev, 1901; Beth, 1936), who succeeded in detecting the radiation pressure acting on macroscopic objects. However, the magnitude of these effects was so small to be consider them irrelevant for any practical use (Ashkin, 2000). Indeed, after the invention of the laser (Townes, 1999) the light forces came back to the attention of scientists, mainly for the possibility to cool and confine atoms (Ashkin, 1970a,b).

Optical tweezers were proposed and demonstrated by Arthur Ashkin (Ashkin et al., 1986; Jones et al., 2015), who has been awarded the 2018 Nobel Prize in Physics (half of the prize). Optical Tweezers are essentially a tightly focused laser beam that can hold and manipulate a microscopic particle in the high-intensity region that is formed at the focal spot. The magnitude of the

forces generated can vary from tens of piconewton down to few femtonewtons. Before Optical Tweezers tiny forces were exerted by Atomic Force Microscopes but limited to few tens of piconewtons. It is clear that Optical Tweezers extended the range of applicability of already existing techniques, like Atomic Force Microscopy, toward weaker forces and, therefore, opened to a myriad of new experiments.

First experiments demonstrated optical trapping and manipulation on individual tobacco mosaic virus and *Escherichia coli* bacterium (Ashkin et al., 1990). Later, the use of optical force spectroscopy to characterize the mechanical properties of biomolecules and motor proteins was developed (Block et al., 1990; Bustamante et al., 1994; Finer et al., 1994). Optical traps allowed biophysicists to observe the forces and dynamics of nanoscale motors at the single-molecule level (Bustamante et al., 2003; Neuman and Nagy, 2008). Since then, optical tweezers have also proven useful in many other areas of physics (Grier, 2003; Molloy and Padgett, 2002; Pesce et al., 2005, 2011; Dholakia et al., 2008; Jonáš and Zemánek, 2008; Juan et al., 2011; Dholakia and Čižmár, 2011; Padgett and Bowman, 2011; Padgett and Di Leonardo, 2011; Polimeno et al., 2018), nanotechnology (Maragó et al., 2013), chemistry (Yi et al., 2006), soft matter (Löwen, 2001; Petrov, 2007; Fusco et al., 2007), and nanothermodynamics (Gieseler and Millen, 2018).

Optical tweezers are not only able to manipulate microscopic objects, but, as it will be described below, are force transducer since their force, at first approximation, is the same of a spring, that is, proportional to the displacement from the equilibrium position. Thus, they can be used to measure the external forces applied to the trapped object. This is the basis of a new kind of scanning probe microscopy using an optically trapped particle as a probe. This technique was later called photonic force microscopy (Ghislain and Webb, 1993; Florin et al., 1997).

The range of optical tweezers applicability has been greatly expanded by the use of advanced beam-shaping techniques, where the structure of an optical beam is altered by a diffractive optical element (Dufresne and Grier, 1998), e.g., to produce multiple optical traps at definite positions (Dholakia and Čižmár, 2011; Padgett and Bowman, 2011). With this techniques it is also possible to generate more complex trapping configuration, e.g., using Laguerre-Gaussian beams, which can produce torques by the transfer of orbital angular momentum (He et al., 1995; Simpson et al., 1996; Piccirillo et al., 2013).

Theory of optical trapping

The conservation of electromagnetic momentum during the scattering process is the basis of the force exerted by light on matter. The general understanding of optical forces is related to approximations based on the ratio between the radiation wavelength and the size of the object illuminated. In fact, when the particle size is much bigger or much smaller than the wavelength of the light, the calculation of the force exerted is greatly simplified. In this case there are two well defined regimes: the geometrical ray optics regime (Ashkin, 1992; Callegari et al., 2015), the dipole approximation regime (Chaumet and Nieto-Vesperinas, 2000). However, when the particle dimensions are comparable with the optical wavelength, that is, the so called intermediate regime, a complete wave-optical modeling of the particle-light interaction is necessary for calculating the optical forces. The Lorenz-Mie theory can be used, for spherical particles, to generate accurate numerical results for essentially any size and refractive index (van de Hulst, 1957; Gouesbet and Gréhan, 2011). Fig. 1 provides an illustration of the range of sizes, shapes and inhomogeneous structures and compositions of objects that have been successfully manipulated in optical tweezers.

In the case of more complex non-spherical particles, e.g., elongated particles, optically anisotropic particles, and inhomogeneous particles (Borghese et al., 2007a) the theory is much more complex. In optical trapping experiments complex objects from tens of nanometers to tens of micrometers are manipulated, and cells, biological structures, metallic, dielectric or hybrid structures are often

Fig. 1 Typical objects that can be trapped in optical manipulation experiments. The trapping wavelengths are in the visible or near-infrared spectral region.

in the middle of the two extreme regimes or from spherical shapes. Thus, in most cases full electromagnetic calculations need to be used to have a correct prediction of the optical trapping behavior.

Geometrical ray optics regime

In many physical problems, approximations are a valuable source of physical insight that can give answers to complex problems. The range of validity of these approximate approaches is determined by the *size parameter* of the particle, defined as:

$$\zeta = 2\pi a n_m / \lambda_0, \quad (1)$$

where a is the characteristic size of the particle (e.g., the radius in the case of a sphere), λ_0 the trapping wavelength in vacuum, and n_m the refractive index of the surrounding medium. Ray optics is valid when $\zeta \gg 1$ and, furthermore, its accuracy increases as the size-parameter grows (Ashkin, 1992; Callegari et al., 2015). By comparison, all exact theories for non-spherical particles becomes unpractical when the size parameter exceeds a certain threshold. This makes ray optics an extremely useful and effective approach when dealing with large (relative to the optical wavelength) particles.

Let us consider a particle with a refractive index n_p , immersed in a homogeneous, non magnetic, non dissipative medium with refractive index $n_m < n_p$, and illuminated by a laser beam with vacuum wavelength λ_0 and hence wavenumber $k_m = 2\pi n_m / \lambda_0$ in the medium surrounding the particle. In the ray optics regime, the optical field may be described as a collection of N rays, each of which is associated with a portion, P_i , of the incident power, $P = \sum_i P_i$, and carries a linear momentum $n_m P_i / c$.

When a single ray impinges on the surface of a dielectric object sphere at a certain angle, a small portion of the power associated to the ray is reflected by the surface while the remaining portion (most of the total power) is refracted inside the sphere. Therefore, let r_i , r_r and r_t be the incident, the reflected and the transmitted rays respectively (see Fig. 2). After being transmitted, r_t travels inside the sphere until it reaches the surface. Again, a small portion will be reflected inside the sphere and the large portion will be transmitted outside. The ray that remains inside the sphere will reach, again, the surface and another scattering event occurs. It is clear that these processes will have place until all the total power of the impinging ray r_i has run off the sphere. Considering these multiple reflection and refraction events the optical force can be calculated directly as (Callegari et al., 2015):

$$\mathbf{F}_{\text{ray}} = \frac{n_m P_i}{c} \hat{\mathbf{r}}_i - \frac{n_m P_r}{c} \hat{\mathbf{r}}_{r,0} - \sum_{j=1}^{+\infty} \frac{n_m P_{t,j}}{c} \hat{\mathbf{r}}_{t,j}, \quad (2)$$

where $\hat{\mathbf{r}}_i$, $\hat{\mathbf{r}}_{r,j}$ and $\hat{\mathbf{r}}_{t,j}$ are unit vectors representing the direction of the incident ray and the j^{th} reflected and transmitted rays, respectively, calculated using Fresnel's reflection and transmission coefficients. Generally, most of the momentum transferred from the ray to the particle is due to only the first two scattering events, especially for small angle of incidence.

The force $\mathbf{F}_{\text{ray}}$ in Eq. (2) has components only in the plane of incidence (Fig. 2) and can be split in two perpendicular components. The component in the direction of the incoming ray $\hat{\mathbf{r}}_i$ represents the *scattering force*, $\mathbf{F}_{\text{ray}, s}$, that pushes the particle in the direction of the incoming ray ($\hat{\mathbf{r}}_i$). The component perpendicular to the incoming ray is the *gradient force*, $\mathbf{F}_{\text{ray}, g}$, that pulls the particle in a direction perpendicular to that of the incoming ray ($\hat{\mathbf{r}}_{\perp}$).

The scattering and gradient forces of a circularly polarized ray on a sphere were derived by Ashkin (1992):

$$F_{\text{scat}} = \frac{n_m P_i}{c} \left[1 + R \cos 2\theta_i - T^2 \frac{\cos(2\theta_i - 2\theta_r) + R \cos 2\theta_i}{1 + R^2 + 2R \cos 2\theta_r} \right], \quad (3)$$

$$F_{\text{grad}} = \frac{n_m P_i}{c} \left[R \sin 2\theta_i - T^2 \frac{\sin(2\theta_i - 2\theta_r) + R \sin 2\theta_i}{1 + R^2 + 2R \cos 2\theta_r} \right], \quad (4)$$

where R and T are the Fresnel reflection and transmission coefficient, and θ_i and θ_r are the incidence and transmission angle relative to the scattering of the incident beam.

Fig. 2 Multiple scattering of a light ray impinging on a sphere, for simplicity is depicted the incident plane only. All the reflected and transmitted rays as well as the optical force associated to that light ray lie on this plane.

Fig. 3 Trapping efficiencies for a ray impinging on a sphere in water taking into account all scattering events. The results are shown for the most common material used for synthetic particles.

Instead of the force, is more convenient to use the trapping efficiency, a dimensionless quantity defined as $Q = c/(n_m P_i)$. The trapping efficiencies permit one to quantify how effectively momentum is transferred from the light ray to the particle, the theoretical maximum value that they can reach is 2, corresponding to complete reflection of a ray at normal incidence. Fig. 3 shows the trapping efficiencies of the total force (scattering and gradient forces) for a sphere of different materials in water. It is interesting to note also that these results are independent of the size of the sphere.

To have the total force exerted by the light on the particle, we have to take into account all the rays constituting a highly-focused laser beam, that is a set of many rays that converge at a very large angle. This means that the total force acting on the particle is the sum of all the contributions from each ray forming the beam. For a single-beam optical trap, the focused rays will produce a restoring force proportional to the particle's displacement from an equilibrium position that lies close to the beam waist. Hence, in one direction, x , for very small displacements, we have a harmonic response of the type $F_x \approx -\kappa_x x$, where κ_x is the spring constant or trap stiffness in the x direction and the origin of the axis is taken at the trap equilibrium position.

Dipole approximation regime

When the particle size are much smaller than the wavelength of the light it is possible to assume that they can be approximated as small dipoles, and that fields are homogeneous inside the particles. This sets a range of validity that is expressed by two conditions (Mishchenko et al., 2002):

$$\zeta \ll 1,$$

$$|m|\zeta \ll 1,$$

where $m = n_p/n_m$ is the relative refractive index between the particle, n_p , and the surrounding medium. Note that the condition (ii) needs to be considered with care for instance when dealing with materials with high refractive index.

An incident electromagnetic field E_i induces an electric dipole moment, $\mathbf{p}$, that, for sufficiently small fields, can be expressed in terms of the particle polarizability as

$$\mathbf{p} = \alpha_p(\omega)E_i, \quad (5)$$

where α_p is the complex polarizability of the particle relative to the surrounding medium given by Draine and Goodman (1993).

Without entering in details that are extensively treated in literature (Pesce et al., 2020; Jones et al., 2015), the particle experiences a time varying force whose average is essentially the sum of three contributions that depend on the gradient of the square modulus of the electric field, the time averaged Poynting vector of the electromagnetic field S_i and the time averaged spin density (Albaladejo et al., 2009b; Gao et al., 2017) respectively:

$$\mathbf{F}_{DA} \propto \nabla |E_i|^2 + \sigma_{\text{ext}} S_i - \sigma_{\text{ext}} \nabla \times \mathbf{s}_d, \quad (6)$$

where $\sigma_{\text{ext}} = k \text{Im} \{\alpha_p\} / \epsilon_m$ is the particle extinction cross-section and ϵ_m the relative permittivity of the medium. The first term in Eq. (6) is the gradient force:

$$\mathbf{F}_{\text{grad}}(\mathbf{r}) = \frac{1}{4} \alpha'_p \nabla |E_i(\mathbf{r})|^2. \quad (7)$$

This force is responsible for confinement in optical tweezers. It arises from the potential energy of a dipole immersed in the electric field, and hence it is a conservative force. Since the intensity of the electric field is $I_i = \frac{1}{2} c n_m |E_i|^2$, we can re-write the gradient force in terms of the gradient of intensity as

$$\mathbf{F}_{\text{grad}}(\mathbf{r}) = \frac{1}{2} \frac{\alpha'_p}{c n_m} \nabla I_i(\mathbf{r}). \quad (8)$$

Therefore, particles with positive polarizability, i.e., particles whose refractive index is higher than that of the surrounding medium, are attracted toward the high-intensity region of the optical field (Ashkin et al., 1986), and particles with negative polarizability, i.e., particles whose refractive index is lower than that of the surrounding medium, are repelled by the high-intensity regions, such as at the focal spot of a focused beam.

The second term is the *radiation pressure or scattering force*:

$$\mathbf{F}_{\text{scat}}(\mathbf{r}) = \frac{n_m \sigma_{\text{ext}}}{c} \mathbf{S}_i(\mathbf{r}). \quad (9)$$

It arises from the transfer of momentum from the field to the particle as a result of scattering and absorption processes, as is revealed by the fact that $\mathbf{F}_{\text{scat}}$ is proportional to the extinction cross-section σ_{ext} . This force points in the direction of the Poynting vector, $\mathbf{S}_i$ (Ashkin, 1970a). However, note that this direction not always coincides with the direction of the local field propagation (Bliokh et al., 2014; Triolo et al., 2017).

The last term in Eq. (6) is the so-called *spin-curl force* (Albaladejo et al., 2009a; Gao et al., 2017):

$$\mathbf{F}_{\text{spin}}(\mathbf{r}) = -\frac{1}{2} \sigma_{\text{ext}} c \nabla \times \mathbf{s}_d(\mathbf{r}). \quad (10)$$

In order for this force to arise, the polarization of the field must be non-homogeneous, which may occur, e.g., in the case of high numerical aperture focusing. This force is relatively small compared to the gradient and scattering forces and, therefore, does not usually play a major role in optical trapping experiments. However, it may yield larger effects when considering higher-order optical beams with inhomogeneous polarization patterns such as superpositions of circularly polarized Hermite-Gaussian beams (Marqués, 2014) or cylindrical vector beams (Volpe et al., 2004; Donato et al., 2012; Skelton et al., 2013). Noticeably, these two last terms represent the *non-conservative* components of the optical force.

Electromagnetic theory

The intermediate regime is characterized by a size of the particle that is comparable to the optical wavelength. In the intermediate regime, the dipole and geometrical optics approximations are not strictly valid. Therefore, a full wave-optical modeling of the interaction between light and particles (i.e., light scattering) is required to calculate optical forces and torques. Starting from the laws of conservation of linear and angular momentum, it is possible to derive the resulting optical force and torque from the distribution of the scattered fields. In particular, by exploiting the conservation of linear momentum, the time-averaged optical force exerted by monochromatic light on a particle is found to be (Mishchenko, 2001; Nieminen et al., 2001; Saija et al., 2005; Borghese et al., 2007b):

$$\mathbf{F}_{\text{rad}} = \int_S \bar{\mathbf{T}}_M \cdot \hat{\mathbf{n}} dS, \quad (11)$$

where the integration is carried out over a surface S surrounding the scattering particle. The vector $\hat{\mathbf{n}}$ is the (outwards) unit vector normal to the S , and $\bar{\mathbf{T}}_M$ is the time-averaged Maxwell stress tensor which describes the mechanical interaction of an electromagnetic field with matter, which needs to be defined carefully (Pfeifer et al., 2007). For harmonic fields this quantity is defined in terms of the total fields complex amplitudes, $\mathbf{E}_t$ and $\mathbf{B}_t$, as

$$\bar{\mathbf{T}}_M = \frac{1}{2} \epsilon_m \text{Re} \left[\mathbf{E}_t \otimes \mathbf{E}_t^* + \frac{c^2}{n_m^2} \mathbf{B}_t \otimes \mathbf{B}_t^* - \frac{1}{2} \left(|\mathbf{E}_t|^2 + \frac{c^2}{n_m^2} |\mathbf{B}_t|^2 \right) \mathbf{I} \right], \quad (12)$$

where $\otimes$ represents the dyadic (outer) product, $\mathbf{I}$ is the unit dyadic, and the fields $\mathbf{E}_t = \mathbf{E}_i + \mathbf{E}_s$ and $\mathbf{B}_t = \mathbf{B}_i + \mathbf{B}_s$ are the total electric and magnetic fields resulting from the superposition of the incident ($\mathbf{E}_i, \mathbf{B}_i$) and scattered ($\mathbf{E}_s, \mathbf{B}_s$) fields. Similarly, by exploiting the conservation of angular momentum, the time-averaged radiation torque is found to be (Borghese et al., 2006)

$$\mathbf{T}_{\text{rad}} = - \int_S (\bar{\mathbf{T}}_M \times \mathbf{r}) \cdot \hat{\mathbf{n}} dS. \quad (13)$$

In the far-field region, the expressions for the radiation force and torque can be significantly simplified. By performing the integration over a spherical surface of very large radius, $r \rightarrow \infty$, fast decaying terms in the integration may be neglected and the radiation force and torque are (Mishchenko, 2001; Nieminen et al., 2001; Saija et al., 2005; Borghese et al., 2007b)

$$\mathbf{F}_{\text{rad}} = -\frac{\varepsilon_m r^2}{4} \int \left[|\mathbf{E}_s|^2 + \frac{c^2}{n_m^2} |\mathbf{B}_s|^2 + 2 \operatorname{Re} \left\{ \mathbf{E}_i \cdot \mathbf{E}_s^* + \frac{c^2}{n_m^2} \mathbf{B}_i \cdot \mathbf{B}_s^* \right\} \right] \hat{\mathbf{r}} d\Omega, \quad (14)$$

$$\mathbf{T}_{\text{Rad}} = -\frac{\varepsilon_m r^3}{2} \operatorname{Re} \left\{ \int \left[(\hat{\mathbf{r}} \cdot \mathbf{E}_t)(\mathbf{E}_t^* \times \hat{\mathbf{r}}) + \frac{c^2}{n_m^2} (\hat{\mathbf{r}} \cdot \mathbf{B}_t)(\mathbf{B}_t^* \times \hat{\mathbf{r}}) \right] d\Omega \right\}, \quad (15)$$

where the integration is now carried out over the full solid angle ($\Omega = 4\pi$). These expressions are the starting point for the electromagnetic calculations of optical forces and torques in optical trapping in the intermediate size regime as well as for inhomogeneous and non-spherical scatterers. The key point is to solve the scattering problem by calculating the scattered fields and consequently the Maxwell stress tensor, from which the optical force and torque can be found, as in Eqs. (11) and (13). However, the calculations of forces and torques in this regime can be a complicated and cumbersome procedure (Borghese et al., 2007a); thus various approaches have been developed to handle this problem (Simpson, 2014; Nieminen et al., 2014). Among the different methods, one successful approach is based on the calculation of the transition matrix (T-matrix) (Borghese et al., 2007a); this is particularly useful and computationally effective because it is possible to exploit the rotation and translation properties of the T-matrix to obtain at once optical forces and torques for different positions and orientations of the trapped particles (Nieminen et al., 2001, 2011; Saija et al., 2005, 2009; Borghese et al., 2006, 2007b, 2008; Simpson and Hanna, 2006, 2007; Simpson et al., 2007).

In Fig. 4, we compare the results for the transversal trapping stiffness κ_x for a spherical particle held by an optical tweezers as a function of the particle radius a obtained with the exact electromagnetic calculations (solid line) with those obtained with geometrical optics (dashed line) and with dipole approximation (dotted line). Interestingly, the agreement is quite good also beyond the range of particle sizes where the approximations are strictly valid.

Three regimes but common features

Although the theory is complicated and one has to make use of approximations or numerical calculations there are some general features that are always valid for a single beam optical tweezers:

- the force is dependent on the laser power, the higher the power the stronger the force;
- the force is dependent on the particle size;
- the stable trapping condition occurs when the gradient force is greater than the scattering one;
- the particle refractive index must be greater (within certain limits) than the surrounding medium;
- for small displacements from the equilibrium position the force is proportional to the displacement and the potential is harmonic;
- the trapping stiffness along the direction of the propagation of the light is less than those in the radial direction and the typical ratio is 0.2–0.4 depending on the focusing properties.

Fig. 4 The red solid line represents the exact electromagnetic calculation. The dipole approximation (dashed blue line) works for small spheres ($a \ll \lambda_0$). The geometrical optics approximation (dashed green line) works for large spheres ($a \gg \lambda_0$). The calculations refer to a polystyrene particle with refractive index of 1.59 immersed in water, trapped by a 10 mW infrared laser ($\lambda_0 = 1064$ nm) using an objective with 1.2 NA.

Brownian motion in optical tweezers

The names Optical Tweezers and Optical Manipulation could lead to misunderstanding, especially for people less expert in this field. The term “trapped particle” does not mean that the particle is at rest, immobilized by the “tweezers.” It is important to have in mind that the scenario is that of microscopic world where the fluctuations of the molecules of the surrounding medium are relevant and affect the motion of the trapped particles. In other words the term “trapped” should be regarded as a “confinement” in space more or less strong.

The motion of microscopic particle in a fluid is, the result of the random collisions between the particle and the fluid molecules and is called Brownian motion after the botanist Robert Brown, who gave the first detailed account, in the early 19th century, examining aqueous suspensions of pollen grains, he found that microscopic particles contained within these grains were always in rapid oscillatory motion (Brown, 1828). Brownian motion never ceases even for a system isolated from external perturbations, i.e., it is a phenomenon that happens at thermodynamic equilibrium and is not due to external perturbations. Brownian motion increases as the particle becomes smaller, as the viscosity of the fluid decreases and as the temperature increases, while, at least to a first approximation, it does not depend on the composition and mass of the particle. The resulting Brownian trajectories are very irregular, composed of translations and rotations, to the point that they appear to have no tangent, their velocity is not well-defined and the motion of a particle at one particular instant is independent of the motion of that particle at any other instant.

Therefore when a particle is trapped by an Optical Tweezers it continues to move due to the fluctuations of the medium, but the motion is constrained within a certain volume whose size depends by the trapping stiffness.

Brownian motion can be described as such a random walk: when a particle in a fluid receives an impulse due to a collision with a solvent molecule, its velocity changes, but, if the fluid is very viscous, this change is quickly dissipated so that the net result of an impact is a displacement of the particle; this kind of behavior is typical of systems in the *low Reynolds number regime* (the Reynolds number, Re , is the ratio of inertial to viscous forces) (Purcell, 1977). The cumulative effect of multiple collisions is to produce the random walk of the particle.

The precise form of a Brownian motion is obviously not predictable, since it depends on a sequence of random events. However, analyzing the Brownian motion of several particles, it is possible to identify some average properties, which are deterministic. For example, the *average particle* displacement after h time steps is zero because in each time step the displacement has zero mean. However, the mean particle displacement does not deliver a lot of information about the random walk, but there are other, more informative, average properties. Some of these properties are the basis of the optical tweezers calibration and will briefly discussed below, for a more detailed treatment the reader could refer to the wide literature (Jones et al., 2015; Pesce et al., 2020).

Experimental setup and calibration techniques

The first experimental realization of an optical tweezers was based on a laser beam passing through an objective lens from the bottom, in this way the laser light pushed a particle against the gravitational force realizing optical levitation. A few year later Arthur Ashkin and coworkers demonstrated optical trapping in three dimensions with a setup comprised mainly of three parts: (i) a laser and a microscope whose objective lens tightly focuses the beam realizing the trapping condition, (ii) an imaging system and (iii) a detection system.

Usually a conventional commercial light microscope is used to built an optical tweezers. There are some advantages but also some drawbacks. Commercial microscopes can be modified to host a dichroic mirror before the objective lens to deflect the trapping laser beam into the lens and at the same time to transmit the illumination light to a camera to image the sample. They are easy to use and are optimized to reduce any aberration or distortion of the sample images, but they may be relatively difficult to customize, for example, to add a position sensitive device. Moreover, the optics are usually optimized for visible light and therefore some issues arise when infrared laser sources are used. Finally, commercial microscopes do not offer the level of mechanical stability required for the most sensitive nanometer-scale experiments. Despite the difficulties in the design and construction of a home-made microscope, choosing this option is increasingly popular. These microscopes can be built directly with standard optomechanical components or with the use of a user-designed frame. In these microscopes the access to any part is very easy and with the proper choice of materials and design the mechanical stability is extremely high. It is also worth noting that home-made microscopes are often significantly less expensive than commercial ones (Pesce et al., 2015).

As we discussed above, particle in an optical trap is subjected to elastic forces, i.e., the restoring force is proportional to the displacement of the optically trapped particle from the center of the optical trap, provided this displacement is not large.

The calibration of an optical tweezers entails the determination of the value of the optical trap stiffness, which in general depends on the properties of both the light beam and the particle. The calibration of an optical tweezers is essential to use it as a microscopic force transducer, i.e., to measure and exert forces in the femtonewton and piconewton range.

In principle, the stiffness could be determined from the properties of the focused laser beam and the trapped particle (Neto and Nussenzeig, 2000; Rohrbach, 2005; Dutra et al., 2014; Arzola et al., 2019). Nevertheless, this is in general a cumbersome task because an exact description of the focused beam and its interaction with particles depends on several parameters that are very difficult to know accurately and may vary drastically even within the same experiment. Therefore, the development and improvement of in-situ calibration methods have been very important to extend the practical applications of optical tweezers.

The calibration methods can be classified as either passive or active. Passive methods use information about the Brownian trajectory of a particle trapped in a static optical tweezers, while active methods are based on the analysis of the response of the particle to a known time-dependent perturbation exerted by an external force.

It is worth to be noticed that all methods used to calibrate optical tweezers rely on the knowledge of the particle position in units of length (i.e., meters). However, the detection devices used in optical tweezers setups (e.g., CCD cameras, quadrant photodiodes or position sensitive detectors) provide, usually, signals in pixels or volts. This point is little considered and very often neglected and usually the viscosity of the medium where the particles to be trapped are dispersed is considered as known variable. This, of course, is reasonable in many cases, but it is important to keep in mind that it is necessary to determine the conversion factor from pixels or volts to meters. For CCD camera, the pixel-to-meter conversion factor can be determined by standard microscopy techniques (e.g., by using a target with known dimensions) (Pesce et al., 2015; Jones et al., 2015). For quadrant photodiodes or position sensitive detectors, the volt-to-meter conversion factor can be determined by scanning an optically trapped particle across a (much weaker) detection beam, but this means that at least two beams are required. It is also possible to perform this calibration self-consistently using only the position signal of an optically trapped particle acquired by a photodetector, when the diffusion coefficient D of the particle is known (e.g., when the particle radius, the medium viscosity and the temperature are known). The basic idea is that the knowledge of D determines the scaling factor of the functions of the particle position used in the calibration process.

In the following there is a brief resume of the main calibration techniques used, for a detailed description the readers could refer to the wide literature, see (Pesce et al., 2015; Jones et al., 2015; Gieseler et al., 2021) and references therein. Fig. 5 shows typical calibration for a spherical colloidal particle trapped by a single beam optical tweezers.

Equipartition theorem

The potential associated with an optical trap is to a very good first approximation harmonic, i.e.,

$$U(x) = \frac{1}{2} \kappa_x [x - x_{\text{eq}}]^2, \quad (16)$$

where κ_x is the trap stiffness and x_{eq} is the equilibrium position. Once this hypothesis has been verified, it is possible to use the equipartition theorem, which states that

Fig. 5 (a) Positions of a 1 μm polystyrene particle trapped by a 1060 nm laser with a power of 3.7 mW, the stiffness along the z axis is weaker than those in the radial direction and the shape is ellipsoidal. Analysis of the trap with the three most common techniques (only the z-axis is shown): (b) potential analysis, (c) power spectral density and (d) autocorrelation function. The blue dots are the experimental data and in red the fit using the equations discussed in the section.

$$\langle U(x) \rangle = \frac{1}{2} \kappa_x \langle (x - x_{\text{eq}})^2 \rangle = \frac{1}{2} k_B T, \quad (17)$$

where instead of the ensemble average one can also employ a time average because of the ergodicity of the system.

As in the determination of the potential described above, the experimental data points need to sample the probability distribution so that they do not need to be acquired at high frequency rate or with a fixed time step as long as a sufficient number of independent points is acquired. It is the easiest and simplest method nevertheless the estimation of trapping stiffness is also prone to systematic errors due to the presence of uncorrelated noise (Florin et al., 1998) and it is limited to harmonic potentials.

Potential analysis

This method can be used for any conservative force, in fact, for such a force, it is possible to define a potential at equilibrium $U(x)$ such that $F(x) = -dU(x)/dx$. The probability to find the particle in a specific position x is given by the Maxwell-Boltzmann distribution:

$$\rho(x) = \rho_0 e^{-\frac{U(x)}{k_B T}} \quad (18)$$

where ρ_0 is a normalization factor. Inverting Eq. (18) allows one to obtain the potential function from the probability density function:

$$U(x) = -k_B T \ln(\rho(x)/\rho_0) + U_0 \quad (19)$$

where U_0 is a constant. In practice, acquiring a large number of positions (Pesce et al., 2015; Jones et al., 2015; Gieseler et al., 2021) using the CCD camera or the Quadrant Photodiode (provided these device have been calibrated to give the position in length units) it is very easy to construct and histogram that represents the probability density function and inverting the result according to Eq. (19) the potential of the optical trap. It is worth to be note that, differently from the methods presented in the following, this method does not assume that the optical tweezers potential is harmonic and, therefore, can be used to verify the hypothesis that the optical potential is harmonic, or to probe more complex potentials, but it does not give any information on the dynamics of the trapped particle like the diffusion coefficient.

Mean square displacement analysis

The Mean Square Displacement (MSD) quantifies how a particle moves from its initial position: for ballistic motion, the MSD is proportional to t^2 , for diffusive motion it is proportional to t , and for a trapped particle it saturates to a constant value. For the case of an optically trapped particle the MSD is given by

$$\text{MSD}_x(\tau) = \overline{[x(t+\tau) - x(t)]^2} = 2 \frac{k_B T}{\kappa_x} \left[1 - e^{-\frac{|\tau|}{\tau_0}} \right], \quad (20)$$

where κ_x is the trap stiffness and $\tau_0 = \gamma/\kappa_x$ is the trap characteristic time. The $\text{MSD}_x(\tau)$ features a transition from a linear growth corresponding to a free diffusion behavior at short time scales ($\tau \ll \tau_0$) to a plateau due to the confinement at long time scales ($\tau \gg \tau_0$).

As for the Equipartition method, this technique only applies to harmonic potentials, the computation of MSD is very slow due to the large number of operations and since the experimental errors are correlated, the estimation from least squares results more involved.

Autocorrelation analysis

Another method often employed in characterizing an optical tweezers is the analysis of the Autocorrelation Function (ACF) of the particle position (Bechhoefer and Wilson, 2002; Viana et al., 2002; Gibson et al., 2008). This method is particularly suited when one wishes to deconvolve a more complex time-domain dynamics of the trapped particle from its tracking signal, e.g., in the case of non-conservative effects (Volpe and Petrov, 2006; Volpe et al., 2007; Pesce et al., 2009) and dynamics of non-spherical particles. The position ACF provides a measure of the time it takes for the particle to “forget” its earlier position. As the stiffness increases, the particle undergoes a stronger restoring force and this time decreases. The position ACF is given by

$$C_x(\tau) = \frac{k_B T}{\kappa_x} e^{-\frac{|\tau|}{\tau_{\text{to},x}}}, \quad (21)$$

where κ_x is the trap stiffness and $\tau_{\text{to},x} = \gamma/\kappa_x$ is the trap characteristic time. The experimental ACF can be fitted by a least squares method to the theoretical ACF (Jones et al., 2015) to obtain an estimation of κ_x . By repeating this analysis on several experimental series it is possible to obtain an average value and an uncertainty for $\kappa_x^{(\text{ex})}$, as well as for the $C_{x,k}$.

Applications

In the following, we present a review of the most relevant applications of Optical Tweezers, since their first experimental demonstration, with particular emphasis to the most recent and exciting experiments.

Single molecule and single cell mechanics

The capability of measuring tiny forces was immediately used in biology to study the thermodynamics and kinetics of intramolecular (Woodside and Block, 2014; Schönfelder et al., 2016) or intermolecular interactions (Manosas et al., 2017), to exploit the molecular motors (Spudich et al., 2011), and fundamental problems in nonequilibrium physics (Ritort, 2008; Ciliberto, 2017) as well as the study of elastic properties of biopolymers (Camunas-Soler et al., 2016) and in general to study single-molecule mechanics (Ritort, 2006; Deniz et al., 2007; Neuman et al., 2007; Moffitt et al., 2008; Neuman and Nagy, 2008; Zhang et al., 2013; Capitanio and Pavone, 2013; Miller et al., 2017).

The first seminal works on single-molecule manipulation appeared, as said above, few year after the demonstration of Ashkin (Ashkin et al., 1986) almost 30 years ago (Block et al., 1990; Bustamante et al., 1994; Finer et al., 1994) and since then, the number of applications of single-molecule mechanics has been continuously increasing. Some of the most used experimental schemes are reported in Fig. 6. It is worth noticing that in recent years, the research in this specific field is, also, oriented to step further toward a considerable increase in throughput. In fact, optical tweezers despite providing a superior accuracy with respect to other manipulation and force techniques like magnetic tweezers and atomic force microscopy, suffer the limitation of their still sophisticated setups that can conduct a single experiment at time, mostly with the presence of operators. Desirable future developments will be the parallelization of measurements in optical tweezers either using holographic techniques (Grier and Roichman, 2006), combining single-molecule fluorescence with force-measurement techniques (Candelli et al., 2011; Cordova et al., 2014; Whitley et al., 2017), controlled force resistive pulse sensing (Keyser et al., 2006; Bulushev et al., 2014), and plasmonic trapping (Juan et al., 2011). Finally, a major step would be to apply force spectroscopy techniques to ex-vivo and in-vivo conditions.

Single molecule mechanics is essentially divided in two groups. In the first one can find experiments intended to shed light on the fundamental physics and chemistry problems using large biomolecules as model systems, i.e., polymer physics, chemical reactions, nonequilibrium physics. In the second group the experiments aimed to enlighten specific biological questions like for instance the mechanics of maintenance and regulatory enzymes in the genome, the energetics and kinetics of DNA hybridization.

The literature comprises many specific reviews addressing these fields, see for example (Ritort, 2006; Deniz et al., 2007; Neuman et al., 2007; Moffitt et al., 2008; Neuman and Nagy, 2008; Zhang et al., 2013; Capitanio and Pavone, 2013; Miller et al., 2017; Bustamante et al., 2021). In these reviews it is evident, for the reader, that the single-molecule field is far to be exhausted and the way is still long.

Fig. 6 Some examples of single molecules experiment. (a) a dDNA filament is attached to two beads trapped in different optical traps and stretched; (b) the same experiment as in (a), but in this case the force measurement is easier since one of the two beads is immobilized by a pipette so that the force is measured only by one optical trap; (c) an actin filament is stretched by two optical traps and a bead stuck to a coverslip has a myosin molecules on its surface, providing ATP to the solution the myosin molecule starts to move on the actin filament and its steps result in pulling of the bead on the left trap (see (Finer et al., 1994)); (d) the trapped particle can be put on rotation and the twisting elasticity of the dDNA strand can be measured (Deufel et al., 2007; Ma et al., 2018).

The possibility to trap microscopic objects immediately opened the way to optical manipulation inside living cells (Ashkin and Dziedzic, 1987; Ashkin et al., 1987). In 1989 Block and coworkers (Block et al., 1989) measured the force exerted by a trapped bacteria demonstrating the possibility to trap living organisms.

The manipulation of single cells with optical tweezers has not been extensively investigated as single-molecule manipulation. This is due, essentially, to the fact the living cells have particular shapes, can be deformed and the pulling forces are difficult to quantify. In addition, single cell manipulation with optical tweezers is achievable only on cells in suspension (such as red blood cells, lymphocytes, senescent, stem cells), since adherent cells are more difficult to manipulate. It is important to note that until now single cell manipulation experiments have been carried out in in-vitro environments, it is necessary to expand these techniques to ex-vivo conditions that offer more interesting and relevant possibilities to study cell biology. The recent advances in optical manipulation and techniques like deep learning are promising not only for biology but also for their implications in physiology and medicine.

Statistical physics and colloidal interactions

Despite the huge success of optical manipulation in the world of biology, the very breakthrough has occurred in the physics world with manipulation of particles to study their interactions in a variety of situations. A system composed of particles dispersed in a continuum medium (such as water) is usually named "colloidal system." The size of particles can range from 10 nm up to 10 μm . These particles undergo a continuous motion, the Brownian motion (Brown, 1828; Dhont, 1996) due to the never ending collisions with the solvent molecules. Their properties can be described by statistical physics ensembles, therefore, this make colloidal systems an ideal model to study statistical physics.

The classical description and concepts of statistical physics, like for example entropy, work and heat, in recent years, have been extended to single stochastic trajectories for systems in contact with a heat bath and driven arbitrarily far from thermal equilibrium by means of a well-specified experimental protocol (Seifert, 2012). This new area, called stochastic thermodynamics, gives several relationships between the fluctuating quantities which generalize the classical macroscopic laws of thermodynamics and describe the non-equilibrium energetics of many microscopic systems, such as colloidal particles, polymers, biomolecules, molecular motors, biochemical networks, and microelectromechanical systems (Ciliberto et al., 2013; Ciliberto, 2017). Therefore, stochastic thermodynamics is a solid theoretical framework for applications ranging from single-molecule biomechanics to optimization protocols and the efficiency of microscopic heat engines (see Fig. 7 for an example of two microscopic engines).

Colloidal suspensions have been used to investigate phase transitions between gas, liquid, solid, and crystalline phases (Anderson and Lekkerkerker, 2002; Pusey and Van Megen, 1986), crystal nucleation (Auer and Frenkel, 2001; Elliot et al., 2001; Gasser et al., 2001), glassy states (Pham et al., 2002), and vapor-liquid interfaces (Aarts et al., 2004). They have been also employed in industry to stabilize emulsions (oil in water and water in oil) and foams (Gonzenbach et al., 2006; Zanini et al., 2017). Colloidal interactions play a key role in all these applications, from food industry (Dickinson and McClements, 1995) to nanotechnology (Zerrouki et al., 2008).

Fig. 7 Examples of microscopic engine. (a) A Stirling engine is a heat engine that is operates between different temperatures, resulting in a net conversion of heat energy to mechanical work. Blickle and Bechinger (2012) realized a microscopic version of a Stirling machine using optical tweezers. In that system an isothermal compression was realized changing the trap stiffness keeping the temperature of the medium constant while the instantaneous temperature changing (isochoric process) was realized using an infrared laser beam tuned to the absorption peak of water. (b) A particle immersed in a critical mixture interacts with the laser beam and is attracted toward the center of the beam. The particle has inhomogeneities that have heated by the laser and the increase in the temperature generates a local phase demixing that exerts a force against the trapping force. Once the equilibrium between these forces has been reached the particle rotate around the laser beam Schmidt et al. (2018).

According to Einstein's description of Brownian motion, particles diffusion is characterized by a particle Mean Square Displacement increasing linearly in time (Fickian), and by a Gaussian displacement distribution. However, ground-breaking experiments on colloidal tracers in biological fluids revealed the existence of a third type of diffusion, which is simultaneously Fickian but non-Gaussian. This phenomenon has been, very recently, investigated using a particular optical manipulation system based on optical speckle field (Pastore et al., 2021, 2022).

The main colloidal interactions are: Van der Waals forces, double-layer forces, DLVO theory forces, steric and depletion forces, Critical Casimir forces and hydrodynamic interactions. Optical tweezers provide an ideal tool for probing these interactions.

Critical Casimir forces have a key role in nanoscience and nanotechnology since are quite strong (piconewton range), have an action in the nanometer range, can be fine tuned modifying the temperature of the ensemble or the particle surface chemistry. It is possible to use these forces to manipulate micro and nano-objects or to assemble micro and nano-devices (Marino et al., 2016; Nguyen et al., 2017), but also to drive nanomachines (Schmidt et al., 2018) at the nano and micro-meter scale.

Other colloidal interactions have also been studied using optical tweezers. A direct measurement of Van der Waals have been performed between two isolated optically trapped rubidium atoms (Beguín et al., 2013), this interesting experiment opened the way to the atomic modeling of micro- and nano-structured devices (Woods et al., 2016). Double layer forces can also play an important role in nanotechnology due to their ability to tune the transport and deposition rate of micro and nano-sized particles. Steric forces are important in crucial in chemistry, biochemistry, and pharmacology, since they tune the rates and the activation energies of most chemical reactions. Depletion forces are extensively used to stabilize colloidal solutions by flocculation, to produce the programmable self-assembly of colloidal nanostructures (Cademartiri and Bishop, 2014), and to drive cellular organization (Marenduzzo et al., 2006).

Optical tweezers in air and in vacuum

It is worth to remember that Arthur Ashkin developed the theory and started experiments to manipulate atoms in vacuum (Ashkin, 1970a; Ashkin and Dziedzic, 1977, 1976, 1971). The enormous explosion of research in liquids put in shadows the possibility to manipulate particles in air or, more challenging, in vacuum. The first experiment in air was demonstrated only 10 years after the seminal paper of Ashkin (Ashkin et al., 1986), since then optical tweezers have been employed mainly to study aerosol droplets (Hopkins et al., 2004; Reiner et al., 2006; Power et al., 2012; Cotterell et al., 2014; Haddrell et al., 2017; Kalume et al., 2018).

Nowadays, optical manipulation is oriented toward trapping nanoparticles in high vacuum. This allows to study a well isolated system and to cool the trapped object to very low temperature. It is clear that this paves the way to observe and study the quantum behavior of a macroscopic object, that is much larger than atoms or molecules, at room temperature (Romero-Isart et al., 2010; Chang et al., 2010; Barker and Shneider, 2010).

Such experiments are very interesting and challenging since to observe quantum effects it is necessary to reduce the residual motion of the trapped particle. This must be decreased to the level of single quantum excitation, that is it must be reduced by more than seven order of magnitude. Excellent and promising results have been already obtained by several groups using, mainly, feedback systems (Tebbenjohanns et al., 2019, 2020; Jain et al., 2016; Gieseler et al., 2012; Conangla et al., 2019) or cavity cooling schemes (Delić et al., 2019; Windy et al., 2019; Meyer et al., 2019). Fig. 8 depicts the mechanism based on these two different approaches to reduce the residual motion of levitated particles.

The quantum ground state is the most important goal since it is the fundamental to prepare these system in non-classical quantum states. For non classical systems like atom, ions, molecules and elementary particles this has been already reached (Haroche, 2013; Wineland, 2013; Tüxen et al., 2010; Hornberger et al., 2012). In the case of massive trapped particles in vacuum only very recently it has been claimed (Delić et al., 2020).

Using nanoparticles in quantum regime has the great advantage of their simpler mechanical mode structure with respect to conventional mechanical oscillators that have a series of vibrational modes. Inside nanoparticles, the frequencies of bulk modes are several orders of magnitude higher than those of the center of mass motion. Therefore, usually, one observes only three modes corresponding to the center of mass motion in each dimension.

Optically levitated particles have unique properties not available in traditional nanomechanical resonators. For example, its mechanical properties can be changed rapidly in situ by simple adjustments in the trapping light. This allows to perform free-fall experiments, which provide new opportunities in force sensing (Geraci and Goldman, 2015; Hebestreit et al., 2018) and quantum physics (Stickler et al., 2018). Unlike traditional clamped mechanical resonators, a levitated particle can rotate freely (Arita et al., 2013; Kuhn et al., 2015, 2017; Rahman and Barker, 2017). The rotation can be accelerated to GHz frequencies, faster than any other object (Ahn et al., 2018; Reimann et al., 2018), simply by changing the trapping laser polarization from linear to circular. At these fast rotations, the centrifugal stress is close to the ultimate tensile strength of the material. Hence, levitated particles can be utilized to test material limits on the nanoscale or to study friction at a fundamental level (Manjavacas et al., 2017; Zhao et al., 2012).

These experiment require an extremely high control of all the parameters involved and among these, it is worth to notice the tuning of the interaction of the trapped particle with the environment. Therefore it is clear that trapped nanoparticles in vacuum are suitable to test single particle thermodynamics (Gieseler and Millen, 2018), a field also known as stochastic thermodynamics (Seifert, 2012). Many studies in this field have already been conducted in the *overdamped* regime with optically trapped particles in a liquid medium. In contrast, levitated particles can also operate in the *underdamped* regime and have enabled the first observation of ballistic Brownian motion (Li et al., 2010), the first quantitative measurement of the Kramers turnover (Rondin et al., 2017),

Fig. 8 A levitated microparticle or nanoparticle is an excellent system for precision measurements since it is very well isolated from the environment. These systems could also be used to study macroscopic quantum mechanics, to do that it is necessary to cool the particle to near their quantum limit, which is in the microkelvin regime for typical trapping potentials. The two main cooling methods are based on feedback or on an optical cavity. Feedback cooling, essentially, uses external forces like: (a) additional optical forces (Li et al., 2011) or, (b) electric forces (Millen et al., 2015). These forces are modulated according to the position of the trapped particle, to eliminate its residual motion. These techniques are limited by the position detection system. (b) Cavity cooling, instead, is based on the effect that an optical cavity, when slightly blue detuned with respect of the trapping laser frequency, allows the photons that have adsorbed mechanical energy from the particle to escape, leading to a decrease of the temperature of the particle (Delić et al., 2019; Windey et al., 2019).

experimental tests of fluctuation theorems (Gieseler et al., 2014a; Hoang et al., 2018), and fundamental tests of thermodynamic laws (Debussac et al., 2020).

Since the nanoparticles are isolated from the environment these systems have a very large mechanical quality factor and, hence, the thermo-mechanical noise of these nanomechanical resonators is very low. Thus, trapped nanoparticles in vacuum can be used as nanomechanical sensors for force (Ranjit et al., 2016; Hempston et al., 2017; Blakemore et al., 2019), torque (Hoang et al., 2016), and acceleration (Monteiro et al., 2017). Applications of these sensors are envisioned to detect exotic forces (Rider et al., 2016; Moore et al., 2014), such as non-Newtonian gravity (Geraci and Goldman, 2015), Casimir forces (Canaguier-Durand et al., 2011; Manjavacas et al., 2017; Nie et al., 2013) and torques (Xu and Li, 2017), and gravitational waves (Arvanitaki and Geraci, 2013).

Finally they are also suited to study nonlinear nanomechanical phenomena (Lifshitz and Cross, 2008; Gieseler et al., 2014b; Ricci et al., 2017), in fact, levitated particles are the first systems where nonlinear effects have been witnessed already at the level of thermal fluctuations (Gieseler et al., 2013).

Conclusion

Optical tweezers were proposed by pioneering work by Arthur Ashkin in the 1970s, since then, these tools have been employed in a broad range of applications in life sciences, physics, and engineering. These include accurate force and torque measurement at the femtonewton level, microrheology of complex fluids, single micro- and nanoparticle spectroscopy, single-cell analysis, and statistical-physics experiments. Accordingly to the increasing difficulties and challenges of the experiments, Optical Tweezers have been developed into more and more sophisticated instruments to manipulate microscopic objects contactless with unrivaled precision and accuracy.

In this chapter, the fundamental aspects of the theory have been discussed and some of the most relevant applications have been presented.

After about 35 years the first demonstration the interest is still high and new routes and techniques are under development. The use of metamaterial to construct compact counterparts to a wide variety of classical refractive or reflective optical components this

will allow a strong decrease of the size of current optical tweezers setup that can be easily integrated into more complex devices. Combining optical tweezers with other detection and measurement techniques will certainly improve their versatility and capability. The recent advances in machine learning will be combined with optical manipulation setups to develop autonomous measurement systems to respond to high demand to increase the output, that currently is still strongly dependent on the presence of trained personnel.

Abstract

Topological materials have gained significant attention in condensed matter physics due to their unique electronic and transport properties. Three-dimensional (3D) topological materials are characterized by robust electronic states that are protected by symmetries and exhibit peculiar spin textures. They offer a rich platform for future information technology including spintronics and topological quantum computing. Here, we review the investigation by angle-resolved photoelectron spectroscopy (ARPES) of topological phases such as strong topological insulators, topological crystalline insulators, magnetic topological insulators, and 3D Dirac, Weyl, nodal, and chiral semimetals and address the status of correlated topological insulators and topological superconductors. A special emphasis is laid on examples from the transition metal dichalcogenide family. Moreover, insights from ultrafast pump-probe experiments are reviewed and a brief outlook is provided.

Key points

- ARPES plays a pivotal role as the primary experimental method for investigating the electronic structure and topology of 3D topological materials.
- ARPES reveals topologically protected surface states as well as their origin in the bulk band structure due to its surface and bulk sensitivity, wave vector resolution in 3D, and sensitivity to symmetries.
- Spin resolution and circular dichroism in ARPES offer valuable information about degeneracies, spin-momentum locking, and spin and orbital textures but final-state effects need to be considered.
- ARPES enables conclusions on fundamental aspects of topological materials, such as band inversion, spin-orbit interaction, and the Berry phase.
- The use of ARPES provides insights into exchange splittings, superconducting pairing symmetries, and the robustness of topological surface states, including surface band bending, interface properties, and quantization effects.

- ARPES has unambiguously identified examples for several classes of topological materials with correlated topological insulators and topological superconductors still outstanding.
- Transition metal dichalcogenides introduce additional flexibility in the study of topological materials and offer unique opportunities for exploration.
- ARPES allows conclusions on scattering channels and aids in understanding the behavior of spin and charge carriers in topological materials.
- The application of ultrafast pump-probe ARPES allows for the investigation of unoccupied states, their spin texture, and the dynamics of interactions between bulk and surface states, especially under external stimuli like infrared light. It can be utilized to study the creation of charge and spin-polarized currents as well as the emergence of exotic photon-dressed states in topological materials.
- The development of micro- and nano-ARPES techniques opens up possibilities for studying smallest crystallites and domains while additional in-operando options allow to study the effects of current, voltage, and strain and will enable the exploration of topological phase diagrams comprehensively.

Introduction

Topological phases of matter are an important research area in condensed matter physics due to their unique electronic and transport properties. In direct analogy the broader mathematical concept describing objects, the topology of a system's electronic structure remains unchanged unless the system undergoes a topological phase transition. A change of the number of holes in the object corresponds then to a change in parameters such as the quantity of gapless states in the electronic structure. As such, the electronic states characterizing a nontrivial topological phase are extremely robust and insensitive to smooth changes in material parameters. Most typically, in 3D (2D) systems, these states manifest as highly conductive Dirac cone-like surface (edge) states with unconventional spin textures. Indeed, 2D topological phases such as the quantum Hall, the quantum spin Hall, and the quantum anomalous Hall insulator have been discovered and investigated through their quantized lossless 1D edge channel transport. Similarly, 3D topological phases have mainly been identified by angle-resolved photoelectron spectroscopy (ARPES) studies into the associated topologically protected surface states spanning across the topologically nontrivial band gap, or between so-called "Weyl nodes" which serve as sources of topological charge.

ARPES provides energy and momentum-resolved information about the occupied electronic structure, allowing for the detection of the electronic states that are characteristic of topological insulators (TIs) and other topologically nontrivial systems. The method is highly surface sensitive, thus providing direct access to the protected surface states in addition to the bulk band structure, which are connected through the bulk-boundary correspondence (i.e., the symmetry-mandated presence of surface or edge states at the interface between nontrivial and trivial media). The 3D momentum resolution enables direct observations regarding dimensionality, and ARPES can be combined with spin detection techniques to resolve characteristic spin textures. Moreover, ARPES can be used in time-resolved experiments, allowing for the investigation of the dynamics of topological electronic states under different conditions, such as in response to external perturbations.

While ARPES was crucial in the characterization of the early 3D TIs, further topological classifications have since been populated with experimental evidence of materials exhibiting nontrivial band topology beyond that of the strong TIs, including topological crystalline insulators, 3D Dirac semimetals, and Weyl semimetals and other topological systems, each possessing unique electronic properties and spin textures. Together, topologically nontrivial materials are at the forefront of the research and development of next-generation information technologies with electronic, spintronic, and quantum computing applications.

In the present chapter, we will address the different types of topological materials in the light of their investigation by ARPES. We will highlight where ARPES can provide insight and which aspects of topological materials facilitated or enabled key ARPES experiments. Likewise, topological materials for which ARPES data are not available are not discussed. For an introduction to the ARPES method, the reader is referred to excellent reviews such as the one by [Comin and Damascelli \(2015\)](#). A recent introduction to ARPES with a chapter on topological materials was published by [Zhang et al. \(2022\)](#) while the review by [Lv et al. \(2019\)](#) of ARPES of topological materials has a focus on instrument aspects. ARPES of quantum materials including topological materials has been reviewed by [Sobota et al. \(2021\)](#) and spin-resolved ARPES of topological materials by [Dil \(2019\)](#). Topological materials are introduced in other chapters of the present volume as well as in prominent review articles ([Hasan and Kane, 2010](#); [Qi and Zhang, 2011](#)). Further review articles are pointed out in the individual paragraphs below.

Topological insulators

Prototypical strong topological insulators

3D TIs behave as a bulk insulator and a surface conductor simultaneously. Their insulating bulk property is due to an inverted band structure between the valence band and the conduction band, typically mediated by the spin-orbit interaction, and their metallic

surface is due to gapless surface Dirac cones with spin-momentum locked spin textures, protected by time-reversal symmetry. This is the situation of strong TIs in the $\mathbb{Z}_2$ class (Hasan and Kane, 2010; Qi and Zhang, 2011).

The bulk-boundary correspondence, responsible for the enforced existence of these topological surface states (TSSs), ensures a coupling between the bulk and the surface. This can be exploited in the verification and characterization of the topological properties of a material. The number of band inversions within the bulk corresponds directly to the number of Fermi-level crossings of individual spin subbands at the surface. Therefore, the topology of a material can be directly determined from the enumeration of Fermi-level crossings along the relevant momentum paths in ARPES data, further cementing the technique as an invaluable tool in the characterization of ground-state electronic structures.

A strong 3D TI phase was experimentally discovered by ARPES and spin-resolved ARPES in the $\text{Bi}_{1-x}\text{Sb}_x$ semiconducting alloy system, demonstrating the existence of nontrivial band topology in a 3D material for the first time (Hsieh et al., 2008). The topological classification, as subsequently confirmed (Nishide et al., 2010; Benia et al., 2015), was identified by a nontrivial $\mathbb{Z}_2$ topological invariant $\nu_0 = 1$, describing an odd number of Dirac cones, distinguishing strong $\mathbb{Z}_2$ TIs from trivial or topologically weak materials where the number of Dirac cones is instead even or zero ($\nu_0 = 0$).

In ARPES, the distinct properties of a 3D TI can be experimentally verified by observing the circular Fermi surface contours around time-reversal invariant momenta or by directly observing their Dirac-like energy-momentum dispersion and spin texture. For a strong $\mathbb{Z}_2$ TI, these signatures must be consistent with an odd number of Fermi-level crossings on the surface, an odd number of band inversions in the bulk, and Dirac-cone TSSs with a chiral, momentum-locked spin texture that fulfill a Berry phase of π . This condition also holds in the cases where the band inversion does not occur at the Fermi level, instead requiring the quantification of crossings in the constant energy contour where the inversion takes place. However, the system will not benefit from the conductive surface states in transport.

The most prominent examples of strong $\mathbb{Z}_2$ TI materials are Bi_2Se_3 , Bi_2Te_3 , and Sb_2Te_3 which were theoretically predicted (Zhang et al., 2009) and subsequently experimentally verified by ARPES (Bi_2Se_3 by Xia et al., 2009 and Chen et al., 2009 and Sb_2Te_3 by Wang et al., 2010) and spin-resolved ARPES (Bi_2Te_3 by Hsieh et al., 2009). An overview of the topologically nontrivial electronic structure of these materials is highlighted in Fig. 1 following their first theoretical prediction. The real-space crystal structure of these compounds consists of 2D van der Waals bonded layers of formula units X-M-X-M-X ($\text{X} = \text{Se, Te}$; $\text{M} = \text{Bi, Sb}$). Compared with the $\text{Bi}_{1-x}\text{Sb}_x$ alloy series, these layered stoichiometric compounds possess a much simpler electronic structure with only one bulk-band inversion, a considerably wide band gap (which has been characterized as direct in Bi_2Se_3 using ARPES; Nechaev et al., 2013), and surface states that form a single gapless Dirac cone at the $\bar{\Gamma}$ point of the surface Brillouin zone.

As shown in Fig. 1 for Bi_2Se_3 , these gapless TSSs are directly observed in ARPES as single band features which disperse linearly between the bulk valence and conduction bands across the topologically nontrivial band gap of ≈ 0.3 eV, a value exceeding the energy scale of room temperature. The 2D nature of TSSs is verified by their lack of dispersion with the electron wave vector k_z perpendicular to the surface, which in ARPES is varied by the photon energy, in contrast to bulk bands that are permitted to disperse in 3D. The bulk band gap is caused by strong spin-orbit coupling driving a band inversion at the bulk Γ point. The resulting single Dirac cone TSS exhibits a pronounced linear energy-momentum dispersion, $E(k_x, k_y) \propto |k|$, and a chiral spin texture in which electron spins are locked perpendicular to their linear momenta and parallel to the surface plane. This spin texture was first measured by spin-resolved ARPES on Bi_2Te_3 (Hsieh et al., 2009). Extensive spin-resolved ARPES measurements (Pan et al., 2011; Souma et al., 2011; Xu et al., 2011; Jozwiak et al., 2011) identified and confirmed the predicted ground-state spin structure of the TSS in Bi_2Se_3 , as shown in Fig. 2. These measurements revealed an in-plane spin orientation tangential to the Dirac cone, with a left-handed chirality that reverses direction below the spin-degenerate Dirac point. For Sb_2Te_3 , the spin texture of the lower Dirac cone has been probed (Pauly et al., 2012).

Bi_2Se_3 and Bi_2Te_3 are intrinsically n -doped so that the chemical potential is in the bulk conduction band while Sb_2Te_3 is slightly p -doped. With ternary compounds $(\text{Sb}_{1-x}\text{Bi}_x)_2\text{Te}_3$ (Kong, 2011) and quaternary compounds $(\text{Bi}_{1-x}\text{Sb}_x)_2(\text{Te}_{1-y}\text{Se}_y)_3$ (Arakane et al., 2012) a fully bulk-insulating or intrinsic 3D-TI phase is achieved leading to surface-dominated conduction in electrical transport at room temperature. Moreover, the quaternary compound allows to control the energy of the Dirac point in the bulk band gap. ARPES is very useful to judge the effect of the doping, though surface band bending has to be taken into account (Analytis, 2010).

Hexagonal warping

In a topologically nontrivial analog of a free electron gas, a TSS would be entirely circular. In real systems, this is often not the case, with the shape of the surface state able to reflect the underlying crystal symmetries (Fu, 2009). The degree of warping is correlated to the localization of the orbitals composing the band inversion and the topological state. In the Bi_2Se_3 material class, this manifests in a hexagonal warping of the constant energy contours of the surface state, usually developing apexes along the $\bar{\Gamma}-\bar{K}$ direction. This warping, which is captured by the third-order correction to the Rashba Hamiltonian, opens an otherwise symmetry-forbidden out-of-plane spin component along the $\bar{\Gamma}-\bar{K}$ direction.

Indeed, ARPES has discovered a snowflake-like, hexagonally warped constant energy surface for Bi_2Te_3 (Chen et al., 2009) (see Fig. 3). This opens possibilities for realizing a number of interesting phenomena, such as a surface quantum Hall effect under applied magnetic fields parallel to the surface, anisotropic surface scattering, or the formation of spin-density waves. As shown in Fig. 3, the hexagonal warping causes a strong anisotropy between the energy-momentum dispersions of the TSS along the $\bar{\Gamma}-\bar{K}$ and $\bar{\Gamma}-\bar{M}$ directions of the surface Brillouin zone, as observed by ARPES.

Fig. 1 Prototypical topological insulator Bi_2Se_3 . (A) The structure consists of quintuple layers (red box) as seen by (B) transmission electron microscopy. Bi_2Se_3 shows a single Dirac cone surface state at the center of the (C) surface Brillouin zone. (D) The band inversion occurs due to the spin–orbit interaction included in the rightmost column. (E) The parity of the band at the Γ point for the four materials Sb_2Se_3 , Sb_2Te_3 , Bi_2Se_3 , and Bi_2Te_3 . The parities of fourteen occupied s and p bands are shown, and of the lowest unoccupied band. The product of the parities for the 14 occupied bands is given in parentheses on the right of each row. All of these systems, except for Sb_2Se_3 , which has the lowest spin–orbit interaction, are topological insulators. (F,G) Surface band structure calculations show a Dirac cone surface state for Bi_2Se_3 and not for Sb_2Se_3 . (H) Observation of the Dirac cone of Bi_2Se_3 by ARPES at $\hbar\nu = 22$ eV. Panels (A), (C)–(G) From Zhang H, Liu C-X, Qi X-L, Dai X, Fang Z, and Zhang S-C (2009) Nature Physics 5: 438; (B) from Springholz G, et al., unpublished; (H) from Xia Y, Qian D, Hsieh D, Wray L, Pal A, Lin H, Bansil A, Grauer D, Hor YS, Cava RJ, and Hasan MZ (2009) Nature Physics 5: 398.

Fig. 2 Orbital-dependent spin texture of Bi_2Se_3 . The photoemission signal of (A) constant energy surfaces and (B) band dispersion of (C) the Dirac cone depends on the direction of the polarization vector ($\mathbf{E}$ marked in panel (A)) (Cao et al., 2013). With s-polarized light, the orientation of in-plane p_x, y orbitals can be determined using experimental geometries where a crystal mirror plane is along or perpendicular to the orbital axis. With p-polarized light predominantly p_z orbitals are probed. (C) The result of the experiments in (A,B) is given in a sketch. (B) The intensity asymmetry for p-polarized light is due to the finite incidence angle of the light. (D–F) Modern spin-resolved photoemission instruments provide complete spin-resolved constant energy surfaces and band dispersions. This is shown for (D) the Rashba-split surface state on Au(111) (Tusche et al., 2015), which shows spin-momentum locking but is not topological. (G) Spin-resolved ARPES has shown that the different p -orbital components have spin textures of opposite in-plane orientations (Xie et al., 2014) which is demonstrated with state-of-the-art data in panels (E,F) (Meyerheim and Tusche, 2018). The overall spin texture corresponds to the one of p_z orbitals probed by p-polarized light. Panels (A–C) from Cao Y, Waugh JA, Zhang X-W, Luo J-W, Wang Q, Reber TJ, Mo SK, Xu Z, Yang A, Schneeloch J, Gu GD, Brahlek M, Bansal N, Oh S, Zunger A, and Dessau DS (2013) Nature Physics 9: 499; (D) from Tusche C, Krasnyuk A, and Kirschner J (2015) Ultramicroscopy 159: 520–529; (E, F) from Meyerheim HL and Tusche C (2018) Physica Status Solidi (RRL) 12: 1800078; and (G) from Xie Z, He S, Chen C, Feng Y, Yi H, Liang A, Zhao L, Mou D, He J, Peng Y, Liu X, Liu Y, Liu G, Dong X, Yu L, Zhang J, Zhang S, Wang Z, Zhang F, Yang F, Peng Q, Wang X, Chen C, Xu Z, and Zhou XJ (2014) Nature Communications 5: 3382.

Following the first theoretical description of this effect, the influence of hexagonal warping on the band dispersion and spin texture of the TSS in Bi_2Te_3 was confirmed by spin-resolved ARPES measurements (Souma et al., 2011). The experiments revealed a left-handed 3D spin texture with an out-of-plane spin component oscillating around the Fermi surface and an in-plane spin component tangentially following the snowflake contour (Chen et al., 2009) resulting from strong warping. The measured out-of-plane spin polarization was found to increase in magnitude with higher binding energy, to reverse sign with an angular

Fig. 3 Hexagonal warping in Bi_2Te_3 . The warping was observed in ARPES at first by [Chen et al. \(2009\)](#). (A–C) Band dispersions and constant-energy surfaces showing the evolution of a circular Dirac cone to a strongly warped one at the Fermi energy. The warping is outward along the $\bar{\Gamma} - \bar{M}$ direction. (D–G) Influence of warping on the spin texture. Panels (A–C,E) from [Sánchez-Barriga J, Scholz MR, Golias E, Rienks E, Marchenko D, Varykhalov A, Yashina LV, and Rader O \(2014a\) Physical Review B 90: 195413](#); (D,F,G) from [Souma S, Kosaka K, Sato T, Komatsu M, Takayama A, Takahashi T, Kriener M, Segawa K, and Ando Y \(2011\) Physical Review Letters 106: 216803](#); (H) from [Hasan MZ, Lin H, and Bansil A \(2009\) Physics 2: 108](#).

periodicity of $\pi/3$ around the hexagonally distorted constant-energy contours, and vanish along the $\bar{\Gamma} - \bar{M}$ direction due to mirror symmetry ([Souma et al., 2011](#)). The influence of warping on the spin orientation was predicted to alter the channels for quasiparticle scattering ([Fu, 2009](#)), and ARPES measurements ([Sánchez-Barriga et al., 2014a](#)) showed that it introduces an anisotropy in the lifetime broadening of the TSS, which is larger along the $\bar{\Gamma} - \bar{K}$ direction.

Warping effects can also be induced in systems which possess many bands with significant k_z dispersion, regardless of the strength of the coupling to underlying bulk symmetries. In these cases, the surface electronic structure adopts unconventional band

dispersions to avoid the energy cost associated with becoming resonant with the bulk bands (see, for example, both topologically trivial and nontrivial surface states in transition metal dichalcogenide (TMD) systems in Section “Case study: Transition metal dichalcogenides”).

Spin and orbital texture and final-state effects

It has frequently been suggested that circular dichroism in the angular distribution (CDAD) of ARPES encodes direct information regarding the spin texture of TSSs (Wang et al., 2011). Circularly polarized light couples, however, mainly to the orbital angular momentum. This is being employed, for example, in x-ray magnetic circular dichroism (XMCD) and in soft-X-ray absorption experiments, where the selection rules for total angular momentum are exploited to access both the spin and orbital magnetic moment (van der Laan and Figueroa, 2014). While one could argue that CDAD may give information on the spin texture where it coincides with the orbital texture (Dil, 2019), it would be desirable to conclude from CDAD the orientation of the orbital moment relative to the spin (Park et al., 2012; Jung et al., 2011). The CDAD of the TSS of Bi_2Te_3 varies, however, strongly with the photon energies and changes sign several times (Scholz et al., 2013). Similar behavior indicating that the CDAD is a final-state effect was observed for Rashba-type spin textures in topologically trivial materials (Ärrälä et al., 2013; Crepaldi et al., 2014). One-step model photoemission calculations including the final state reproduced the sign changes in the CDAD and indicated also a behavior with photon energy different from that of the in-plane spin polarization (Scholz et al., 2013).

A combination of complementary techniques is often required for a full, unambiguous characterization. While initially spin-resolved ARPES experiments provided contradictory values for the in-plane spin polarization of the TSS, for example, in Bi_2Se_3 there is agreement that the measured in-plane spin polarization matches the theoretical prediction of $\sim 50\%$, reduced from 100% due to spin-orbit interaction (Yazyev et al., 2010). By studying the response of the measured spin properties to incident light and its polarizations, it is possible to gain further experimental insight into the spin texture of TSSs. Several experimental and theoretical works have investigated the effect of varying photon energy and light polarization on the chiral spin texture of TSSs, which has revealed that it can be decomposed into individual orbital contributions from different atomic layers. Through an analysis of the initial states and their orbital character, it has been demonstrated that the total spin texture of the TSS in Bi_2Se_3 is a linear combination of the distinct spin textures associated with each individual orbital component, namely, the two opposite spin textures deriving from the out-of-plane p_z and in-plane p_x, y orbitals, see Fig. 2. This phenomenon can be attributed to strong spin-orbit coupling, and the resulting spin textures compiled from the orbital-specific contributions were coined “coupled spin-orbital textures” (Zhang et al., 2013; Cao et al., 2013; Zhu et al., 2013). Since the dominant orbital character in the wave function of the TSS is p_z , this leads to a partial reduction in the magnitude of total spin polarization ($<100\%$).

This property has been compared for the more isotropic Dirac cone of $\text{Bi}_2\text{Te}_2\text{Se}$ and the warped Dirac cone of Bi_2Te_3 (Bentmann et al., 2021). For the isotropic Dirac cone, the measured momentum distribution of the photoemission intensity and the spin was found to qualitatively reflect the orbital composition and orbital-projected in-plane spin polarization, respectively. This was also observed for the in-plane spin polarization of Bi_2Te_3 . However, the out-of-plane spin polarization of Bi_2Te_3 has been found to change with photon energy (Seibel et al., 2016; Bentmann et al., 2021), which was qualitatively confirmed by one-step photoemission calculations (Bentmann et al., 2021).

Furthermore, due to the fact that the wave function of the TSS extends deep into the bulk (about 2 nm) and the orbital weights change with distance from the surface, the total spin texture can also be broken down into contributions from different atomic layers (Zhu et al., 2013). As a result, a layer-dependent spin-orbital texture is observed, with a significant out-of-plane p_z -orbital contribution within the first five atomic layers (Se-Bi-Se-Bi-Se, or a quintuple layer, about 1 nm) while only a relatively small in-plane $p_{x,y}$ contribution is present except for the fifth atomic layer. It has been argued that this layer dependence is responsible for the photon energy dependence of the spin polarization via quantum interference (Zhu et al., 2013, 2014).

A theoretical study suggested that the spin texture of the photoelectrons may differ from that of the TSSs due to a strong spin-flip effect during photoemission (Park and Louie, 2012). This effect was later experimentally confirmed by a spin-resolved ARPES experiment on Bi_2Se_3 using a 6-eV laser source (Jozwiak et al., 2013), see Fig. 4. This raised the question of whether the use of linearly or circularly polarized light will always rotate the spins of the Dirac cone in the photoemission process along the propagation direction of the incident light, controlling their orientation through the direction of light polarization. According to another spin-resolved ARPES experiment, the measured spin texture of photoelectrons reflects the total spin texture of the TSSs in the initial state (which for Bi_2Se_3 is in plane) for various geometries, photon energies, and light polarizations, indicating that the predicted final state spin-flip effect is a weak perturbation (Sánchez-Barriga et al., 2014b). The relative importance of this effect ultimately depends on the final state the electron.

As shown in Fig. 4 for Bi_2Se_3 , these experimental findings were consistent with one-step model photoemission calculations demonstrating that when vacuum ultraviolet photons with linear or circular polarization are used under different incident geometries, the magnitude and direction of the measured photoelectron spin polarization remain unchanged and independent of the light polarization in the photon energy range 50–70 eV. Accordingly, the observed spin texture of the photoelectrons is consistent with the chiral, momentum-locked, in-plane spin texture of the TSS in the initial state, and the magnitude of total spin polarization corresponds to the theoretically predicted value in the ground state ($\approx 50\%$). For very low photon energies of 6 eV, however, circularly polarized photons flip the photoelectron spins perpendicular to the surface and reverse the resulting out-of-plane spin texture of the photoelectrons with the sense of circular polarization (Jozwiak et al., 2013). The conditions for light-induced spin manipulation at low photon energies are determined by dipole selection rules, which allow transitions into s-like final

Fig. 4 Spin texture of photoelectrons from the Dirac cone of Bi_2Se_3 . (A) ARPES dispersion using 6 eV laser light and (B,C) corresponding out-of-plane spin polarization for opposite circular light polarization. (C) Dispersion at 50 eV photon energy for linear light polarization and corresponding spin-resolved ARPES measurements for circular light polarization at (D) 50 eV and (E) 6 eV. (F) One-step-model photoemission calculations. At 50 eV, the photoelectron spin polarization corresponds to the in-plane ground-state spin texture while at 6 eV, the out-of-plane spin polarization reverses with the circular light polarization. (G) Simplified sketch of the experimental and theoretical results. Panels (A,B) from Jozwiak C, Park, C-H, Gottlieb K, Hwang C, Lee D-H, Louie SG, Denlinger JD, Rotundu CR, Birgeau RJ, Hussain Z, and Lanzara A (2013) *Nature Physics* 9: 293; Panels (C–F) from Sánchez-Barriga J, et al. (2014b) *Physical Review X* 4: 011046.

states. However, this condition is not fulfilled for typical photon energies in the vacuum ultraviolet spectral range, where relevant transitions from the Dirac cone occur primarily into lower symmetry d -like final states. Therefore the original prediction is fulfilled at low laser energies despite the need for much higher photon energies to approximate free-electron-like final states. The final-state wave functions in both cases are the most symmetric and connected to the highest symmetry in the atomic case (i.e., an s -like final state wave function with angular momentum $l = 0$), which is necessary for light-induced spin manipulation. Thus, very low or very high photon energies in the X-ray spectral range are required for light-induced spin manipulation (Sánchez-Barriga et al., 2014b).

Thin limit

The effect of quantum confinement in topological insulators was initially investigated through ARPES experiments on Bi₂Se₃ bulk single crystals, demonstrating that inducing a sufficiently strong band bending is a feasible approach to achieve quantization of the bulk bands in the near surface region of a 3D TI (King et al., 2011). This is shown in Fig. 5A–C, which also demonstrates that the quantized subbands possess a Rashba-type spin splitting due to the surface potential well.

The weak van der Waals bonding of these compounds, leading to a relaxation of the requirement for lattice matching, allows for the growth of ultrathin films on various substrates by molecular-beam epitaxy (MBE), providing unprecedented control over thickness and composition. This advantage enables experimental investigations into the influence of chemical substitution, quantum-size effects, and dimensionality of topological properties. One example is the observation of a gap opening at the surface Dirac point in ultrathin TI films by ARPES, which demonstrates a topological phase transition driven by surface-to-surface tunneling between Dirac cones with opposite spin textures located on opposing film surfaces (Zhang et al., 2010), see Fig. 5D. This has been studied by spin-resolved ARPES (Neupane et al., 2014; Landolt et al., 2014). As demonstrated in Fig. 5E–G, this surface-to-surface coupling modulates the spin texture of the TSS with reducing thickness.

Magnetic topological insulators

Since $\mathbb{Z}_2$ TIs are protected by time-reversal symmetry, a spontaneous magnetization can lead to a magnetic exchange gap at the Dirac point. If the Fermi energy is aligned to the exchange gap, a quantum anomalous Hall effect can occur. Other desirable consequences include the topological magnetoelectric effect, axion insulator, dissipationless electronics and spintronics based on edge states, and the possibility for constructing topological quantum bits, see the review by Tokura et al. (2019).

The ARPES perspective has focused on the verification and measurement of the exchange gap relative to the position of the Fermi energy as well as investigation of the resulting hedgehog-type spin texture. The magnetic exchange gap was indirectly probed by the observation of the quantum anomalous Hall effect (Chang et al., 2013). From the thermal activation of dissipation-free transport, this gap is in the range of only 50–100 μ eV in V- and Cr-doped TIs, orders of magnitude lower than the principal limit set by the Curie temperature (Chang et al., 2015).

Spectroscopic investigations relied on scanning tunneling spectroscopy and ARPES. Early work suffered from a lack of evidence for the closing of the gap above the Curie temperature, a test that, due to stability issues, is easier in ARPES than in scanning tunneling spectroscopy. Another prerequisite for the exchange gap is a perpendicular magnetic anisotropy (see, e. g., Henk et al., 2012), typically not present in Bi₂Se₃-based systems. The reason for the latter is that the spin–orbit interaction has to be high enough so that the magnetocrystalline anisotropy overcomes the shape anisotropy, and this can be achieved by replacing Se by the heavier Te (Rienks et al., 2019). The comparatively lower spin–orbit interaction has also been suggested as a reason why the Bi₂Se₃ systems are susceptible toward the opening of impurity-induced gaps at the Dirac point that are not of magnetic origin (Rienks et al., 2019).

Among early studies that fulfill some of these criteria, scanning tunneling spectroscopy of Cr_{0.08}(Bi_{0.1}Sb_{0.9})_{1.92}Te₃ reported substantial disorder in the size of the exchange gap (Lee et al., 2015), which might be responsible for the low operating temperature of the quantum anomalous Hall effect. ARPES of insulating V-doped (Bi,Sb)₂Te₃ epitaxial films showed that the Dirac point is degenerate with the bulk valence band and it was concluded that this limits the achievable temperature of the quantum anomalous Hall effect (Li et al., 2016). No exchange gap could be found by ARPES down to 7 K (Li et al., 2016) and down to 1 K (Goliias et al., 2021). In both cases, the Dirac point was observed $\approx$ 50 meV below the Fermi level. Cr-doped (Bi,Sb)₂Te₃ was studied by ARPES at 12 K and no exchange gap was found also after increasing the chemical potential through surface *n*-doping by potassium (Kim et al., 2021).

Mn-doped Bi₂Te₃ has perpendicular magnetic anisotropy (Hor et al., 2010) and was later identified as consisting of a natural MnBi₂Te₄/(Bi₂Te₃)_{*m*} heterostructure (Rienks et al., 2019), similar to its selenide counterpart (Hagmann et al., 2017; Hirahara et al., 2017). MnBi₂Te₄ contains a Mn layer in the center of a 7-layer unit (septuple layer). The Mn concentration and the number, *m*, of Bi₂Te₃ quintuple layers can be related by X-ray diffraction. For 6% Mn (i.e., *m* = 2 to 3), a gap at the Dirac point of 90 meV was measured by peak fitting in ARPES at 1 K and of 56 meV at 6.5 K by spin-resolved ARPES which closes at the Curie temperature (Rienks et al., 2019). This is shown in Fig. 6. The closing of the gap at the Curie temperature has been confirmed in two other cases: For a gap of 70 meV at 8 K for 3 and 5 net ferromagnetic quintuple layers of MnBi₂Te₄ (Trang et al., 2021) and for MnBi₆Te₁₃ (i.e., *m* = 3) with septuple layer termination for a 28 meV gap at 7 K (Lu et al., 2021). For MnBi₆Te₁₀ (*m* = 2), three different terminations can be distinguished from the band dispersions (Klimovskikh et al., 2020). Very similar results are obtained by Gordon et al. (2019) and Hu et al. (2020) with mass gaps of the order of 100 meV when MnBi₄Te₇, MnBi₆Te₁₀, and MnBi₈Te₁₃ are terminated by one layer of Bi₂Te₃, see Fig. 6.

A single septuple layer MnBi₂Te₄ has been characterized by ARPES as ferromagnetic trivial insulator (Gong et al., 2019) with a bandgap >780 meV (Trang et al., 2021). This septuple layer MnBi₂Te₄ becomes again topological when in a heterostructure with 4 quintuple layers Bi₂Te₃ and another septuple layer MnBi₂Te₄ (Li et al., 2022).

In stoichiometric bulk MnBi₂Te₄, the Mn layers couple antiferromagnetically to form an antiferromagnetic TI (Otrokov et al., 2019; Gong et al., 2019). The magnetic gap in MnBi₂Te₄ (Otrokov et al., 2019) has been the subject of controversy: Chen et al. (2019)

Fig. 6 Natural heterostructures MnBi₂Te₄/(Bi₂Te₃)_m. (A–E) Terminations with Bi₂Te₃ quintuple layers (QL) and MnBi₂Te₄ septuple layers (SL) have distinct features. (B,D) The Dirac cone appears gapped for 1 QL termination due to hybridization effects. (F) In thin films, the distribution of SL units is random, as seen in transmission electron microscopy. For 6% Mn ($m = 2$ to 3), the Dirac cone (topological surface state, TSS) shows (G) an exchange gap with out-of-plane spin texture which (H) away from the Dirac point develops into the spin-momentum-locked in-plane spin texture. (I) The gap closes at the Curie temperature and follows the macroscopic out-of-plane magnetization. Panels (A)–(E) from Gordon KN, Hongyi S, Chaowei H, Linn AG, Haoxiang L, Yuntian L, Pengfei L, Mackey S, Qihang L, Ni N, and Dessau D (2019) arXiv:1910.13943; (F)–(I) from Rienks EDL, Wimmer S, Sánchez-Barriga J, Caha O, Mandal PS, Růžicka J, Ney A, Steiner H, Volobuev VV, Groiss H, Albu M, Kothleitner G, Michalicka J, Khan SA, Minár J, Ebert H, Bauer G, Freyse F, Varykhalov A, Rader O, and Springholz G (2019) Nature 576: 423.

found a vanishing gap and exchange split bulk states. It is possible that Mn-Bi intermixing (Zeugner, 2019) is responsible for differences in magnetic structure between different samples of MnBi₂Te₄ as well as those of MnBi₂Te₄/(Bi₂Te₃)_m.

Epitaxial films of MnSb₂Te₄ are ferromagnetic TIs with Curie temperatures up to 50 K. The ferromagnetic order contrasts predictions of antiferromagnetism but is explained by Mn excess of the order of 5%. A slight *p*-doping prevents ARPES from measuring the gap at the Dirac point, but in scanning tunneling spectroscopy, the gap is seen to vanish near the Curie temperature (Wimmer et al., 2021).

Among new materials, EuSn₂As₂ was characterized as antiferromagnetic TI by time-resolved ARPES above the Fermi level (Li et al., 2019a). The Weyl semimetal phase of MnSb₂Te₄ (Murakami et al., 2019) and MnBi₂Te₄ (Li et al., 2019b) has not yet been reached without external magnetic field. FeBi₂Te₄ has recently been synthesized (Saxena et al., 2020), and CrBi₂Te₄ and CrBi₂Te₂Se₂ have been predicted as magnetic TIs (Petrov et al., 2021).

Topological crystalline insulators and weak topological insulators

In contrast to the Dirac cones in strong TIs which are protected by time-reversal symmetry, a second class, known as topological crystalline insulator (TCI) exhibit Dirac cones protected by the crystal symmetry itself, see the review by Ando and Fu (2015). An example is the rock-salt-structured $\text{Pb}_{1-x}\text{Sn}_x(\text{Se,Te})$ series, see Fig. 7. Dirac-cone TSSs have been observed by ARPES for SnTe (Tanaka et al., 2012), $\text{Pb}_{0.6}\text{Sn}_{0.4}\text{Te}$ (Xu et al., 2012), and the $\text{Pb}_{1-x}\text{Sn}_x\text{Se}$ series (Dziawa et al., 2012). They possess a chiral spin texture and spin-momentum locking. Since TCIs are protected by individual crystal symmetries and bear a weak topological index, the quantum phase transition in TCIs is vulnerable to external perturbations (Hsieh et al., 2012; Ando and Fu, 2015).

For TCIs, the decisive role of the crystal symmetry renders the topological protection dependent on the specific crystal face (Fu, 2011). The topological invariants allow for an even number of Dirac cones (Fu and Kane, 2007; Fu, 2011). $\text{Pb}_{1-x}\text{Sn}_x\text{Se}$ and $\text{Pb}_{1-x}\text{Sn}_x\text{Te}$ represent a mirror-symmetry-protected TCI phase with fourfold valley degeneracy (Fu and Kane, 2007; Hsieh et al., 2012) in which the trivial-to-TCI phase transition is reached for sufficiently large Sn contents and with reducing temperature (Tanaka et al., 2012; Xu et al., 2012; Dziawa et al., 2012). Upon cooling, the lattice contracts and the enhanced orbital overlap leads to an inverted bulk band gap, which, via bulk-boundary correspondence, gives rise to an even number of spin-polarized Dirac cone surface states with spin-momentum locking, as confirmed experimentally by ARPES (Dziawa et al., 2012) and spin-resolved ARPES (Wojek et al., 2013), see Fig. 7A–F. Since the TSSs in TCIs are only protected by crystal symmetry, they are an ideal platform for manipulating the topological properties. Due to their high sensitivity to external perturbations, the topological phase transition can be controlled by varying pressure, hybridization in ultrathin film geometries, magnetic interactions, or by breaking of mirror symmetry by strain, electrostatic fields, and ferroelectric lattice distortions (Hsieh et al., 2012; Assaf et al., 2014; Tang and Fu, 2014; Zeljkovic et al., 2015; Plekhanov et al., 2014). These properties offer an advantage for topology control not available in $\mathbb{Z}_2$ -TIs, such as to open a gap at particular Dirac points by quantum confinement or unidirectional strain. For SnTe, a topological phase transition from a TCI to a $\mathbb{Z}_2$ -TI by a lattice distortion has been predicted (Plekhanov et al., 2014). Bi doping of $\text{Pb}_{1-x}\text{Sn}_x\text{Se}$ (111) epilayers induces a quantum phase transition from a TCI to a strong $\mathbb{Z}_2$ -TI by lifting the fourfold valley degeneracy via a sublattice shift and rhombohedral distortion along the [111] direction. The phase transition was confirmed by ARPES through the number of gapless Dirac cones (Mandal et al., 2017).

Up to now, most experimental work has been performed on *p*-type bulk single crystals exploiting the natural (001) cleavage plane of the IV–VI compounds, whereas for other surface orientations and actual devices, epitaxial TCI film structures are required. To this end, the (111) orientation is particularly interesting due to the polar nature of its surface. For instance, control of the Fermi level and carrier concentration leading to a giant Rashba effect was achieved for Bi- and Sb-doped TCI $\text{Pb}_{1-x}\text{Sn}_x\text{Te}$ (111) films (Volobuev et al., 2017). Similarly, control of both the topological phase transition and the structure inversion asymmetry additionally was achieved for TCI quantum wells in thin $\text{Pb}_{1-x}\text{Sn}_x\text{Se}$ films grown on $\text{Pb}_{1-y}\text{Eu}_y\text{Se}$ barriers (Rechciński et al., 2021), see Fig. 7G.

The TCIs presented above depend on a symmorphic mirror plane. Symmorphic symmetries preserve the origin whereas nonsymmorphic spatial symmetries translate the origin by a rational fraction of the lattice vector. This leads to new classes of topological crystalline insulators (Liu et al., 2014a), for example, such that lead to a symmetry-protected surface Dirac point that is not pinned to a specific point (Fang and Fu, 2015). In time-reversal invariant nonsymmorphic TIs, instead of surface Dirac fermions, the appearance of surface fermions with hourglass-shaped dispersion was predicted where two pairs of branches switch their partners (Wang et al., 2016b). This behavior was predicted for KHgX ($X = \text{As, Sb, and Bi}$) (Wang et al., 2016b) and was demonstrated by ARPES for the (010) surface of KHgSb (Ma et al., 2017; Liang et al., 2017).

Besides TCIs there is another topological class which leads to TSSs only on particular surfaces. These are weak TIs which are not protected by crystal symmetries but by time-reversal symmetry in the same way as strong topological insulators. They can be considered as 2D quantum spin Hall insulators stacked in 3D. The side surfaces are often difficult to prepare in experiment which renders their confirmation difficult despite several theoretical predictions, e. g. for PbTe/SnTe superlattices (Yang et al., 2014). Bi_1Te_1 , which is a superlattice of 2 quintuple layers of Bi_2Te_3 and one Bi bilayer, has been predicted to be a dual TI, i.e., in this case a TCI and a weak TI. The TSS on the top surface, protected by mirror symmetry, has been confirmed by ARPES but not the TSS on the side surface protected by time-reversal symmetry following the picture of the stacked 2D quantum Hall insulator (Eschbach, 2017). Another prediction for a weak TI concerns $\beta\text{-Bi}_4\text{I}_4$ (Liu et al., 2016). $\beta\text{-Bi}_4\text{I}_4$ consists of stacked molecular chains and shows in ARPES a 1D Dirac cone surface state (Autès et al., 2016). The system has naturally cleavable top and side surfaces. By spatially resolved ARPES, a quasi-1D Dirac cone was found at the side surface (100) whereas the top surface (001) shows no TSS (Noguchi et al., 2019).

Dirac semimetals

3D Dirac semimetals emerge at the quantum critical point of a topological phase transition between a trivial insulator and a $\mathbb{Z}_2$ -TI (Wang et al., 2012b). Closing the bulk band gap in a TI gives rise to a 3D Dirac semimetal phase that can be viewed as the bulk analog of graphene, which is a 2D Dirac semimetal. For Bi_2Se_3 , for example, moving across the topological quantum phase diagram would be done theoretically by continuous control of the spin-orbit coupling strength (Brahlek et al., 2012; Wu et al., 2013).

A linear bulk band crossing exactly at the quantum critical point between topologically trivial and nontrivial phases could be accurately described as a Dirac semimetal, with a single fourfold degenerate 3D Dirac point and linear energy dispersions along all three orthogonal momentum directions. Appropriate tuning of the chemical potential in this case would result in a point-like Fermi surface. However, this crossing point could be destroyed by minute perturbations, pushing the Dirac semimetal to either side of the topological transition to produce a finite gap, see Fig. 8A. Experimentally realized topological Dirac semimetals instead employ intrinsic rotational crystalline symmetries to prevent hybridization between crossing bands, ensuring the formation of robust bulk Dirac points.

Yang and Nagaosa (2014) presented a general framework for classifying stable 3D Dirac semimetals in systems characterized by the presence of time-reversal, inversion, and uniaxial rotational symmetries. Two distinct classes of 3D Dirac semimetals are identified in their study. In one class, the Dirac semimetal exhibits a single Dirac point at a time-reversal invariant momentum on the rotation axis where the band crossing is ensured by the lattice symmetry, see Fig. 8B. In contrast, the other class of Dirac semimetals features a pair of Dirac points on the rotation axis symmetric about the time-reversal invariant momentum, see Fig. 8C. Here, the Dirac points are formed through a band inversion and this class is accompanied by a quantized topological invariant and commonly referred to as 3D topological Dirac semimetals. A further spectroscopic signature is the presence of Fermi arc surface states connecting between bulk Dirac points in topological DSMs (Wang et al., 2012b, 2013b), which were at first discussed in the context of 3D Weyl semimetals (Wan et al., 2011). When the Dirac point acquires a mass gap because of symmetry breaking, the 3D topological Dirac semimetal can turn into either a 3D strong TI or a 3D TCI.

Experimentally, Cd_3As_2 (Borisenko et al., 2014; Ali et al., 2014a; Neupane et al., 2014) and Na_3Bi (Liu et al., 2014b; Xu et al., 2013b) were the first 3D topological Dirac semimetals that were confirmed by ARPES. A highly linear bulk band crossing forming a 3D Dirac cone projected at the Brillouin zone center of the (001) surface of Cd_3As_2 has been observed down to photon energies of about 22 eV (Neupane et al., 2014). A systematic confirmation along all three orthogonal momentum directions followed for Cd_3As_2 and Na_3Bi (Borisenko et al., 2014; Ali et al., 2014a; Neupane et al., 2014; Liu et al., 2014b; Xu et al., 2015c), see Fig. 8. ARPES and spin-resolved ARPES experiments on Na_3Bi revealed a double Fermi arc surface structure, which is spin polarized and confirms the topological protection (Xu et al., 2015c), see Fig. 8L. It has been proposed that Cd_3As_2 and Na_3Bi would transition into a TI state if they are distorted (Wang et al., 2012b, 2013b). This is another interesting aspect that concerns the protection of the 3D Dirac points by the symmetry of the lattice, potentially enabling the switching on and off of their contribution to transport by external perturbations, such as strain or other structural distortions (Wang et al., 2012b, 2013b). Such a topological phase transition would ideally require an intrinsic mechanism by which to induce a structural distortion to be easily accessible by ARPES. Au_2Pb is thought to be a candidate for this purpose, as it naturally undergoes several structural phase transitions with reducing temperature (Schoop et al., 2015).

Breaking inversion or time-reversal symmetry, or both, in a 3D Dirac semimetal is predicted to be a fruitful platform for the observation of topological phase transitions. A direct consequence is that the 3D Dirac points will split into Weyl points of opposite chirality in momentum space.

Nonmagnetic Weyl semimetals

3D Weyl semimetals are a nontrivial state of matter with peculiar low-energy excitations and transport properties (Wan et al., 2011; Balents, 2011; Burkov and Balents, 2011; Hosur and Qi, 2013; Weng et al., 2015; Armitage et al., 2018; Narang et al., 2021). They combine a quasi-relativistic dispersion, which is linear in momentum in all three spatial directions with topological protection (Soluyanov et al., 2015; Huang et al., 2015; Bansil et al., 2016) and exhibit extremely high carrier mobilities, which could enhance the efficiency of future electronic devices (Yang et al., 2011; Sun et al., 2016). Due to their nontrivial topology, 3D Weyl semimetals host spin-polarized topological Fermi arcs at the surface while being metallic in the bulk (Armitage et al., 2018; Narang et al., 2021; Soluyanov et al., 2015; Huang et al., 2015). They offer a rich platform for the realization of an unusually large magnetoresistance (Shekhar et al., 2015) and applications in future electronics and spintronics (Sun et al., 2016).

A 3D Weyl semimetal phase arises from breaking time-reversal symmetry or inversion symmetry in a 3D Dirac semimetal. If in addition the spin-orbit interaction is sufficiently strong such that the bulk bands remain in the inverted regime and gapless, each fourfold degenerate bulk Dirac point in a topological 3D Dirac semimetal will split into two 3D Weyl points of opposite chirality. Hence, for each original Dirac point in the 3D Dirac semimetal, breaking any of the two symmetries leads to a pair of twofold degenerate 3D Weyl cones that are topologically protected and exhibit quasi-relativistic energy dispersion in 3D momentum space. Consequently, the spin-polarized Fermi arcs connecting bulk Dirac points no longer form closed loops in the 3D Weyl semimetal phase. Instead, the surface Fermi arcs connect pairs of 3D Weyl points with opposite chirality, and form open loops when projected on the surface Brillouin zone. The Weyl nodes themselves act as channels through the bulk of the crystal to the opposite surface, thus ensuring a globally closed contour of Fermi arcs. In line with this, Weyl points arise as pairs with opposite chirality. Indeed, the chirality associated with each Weyl point is a topological property defined as a topological charge given by a nonvanishing Chern number, i.e., topological invariant, which means that the Weyl cones can only be moved in energy and momentum space, or tilted, rather than being gapped by external perturbations.

In the case of 3D Weyl semimetals, a minimal setting corresponds to the situation of a 3D Dirac semimetal, but in which time-reversal symmetry is broken while inversion symmetry is preserved. When only inversion symmetry is present, a 3D Weyl point at k

must necessarily be accompanied by a partner node at $-k$ that carries the opposite topological charge at the same energy. This configuration allows for a minimum number of Weyl points with opposite chirality. In contrast, when only inversion symmetry is broken, time-reversal symmetry requires that these two Weyl points at opposite momenta carry the same topological charge. In this situation, because the total topological charge within the entire Brillouin zone should vanish, another pair of Weyl points with the opposite topological charge is additionally required to achieve charge neutrality. A natural consequence is that the Weyl nodes in 3D Weyl semimetals without inversion symmetry must necessarily exist in multiples of four. This fact also provides a convenient way to investigate a variety of interesting effects associated with topological charge redistribution, such as the efficient generation of optically driven spin-polarized currents from highly tilted Weyl cones or other photoinduced responses like the photovoltaic chiral magnetic effect or the gyrotropic magnetic effect.

The first materials confirmed experimentally were inversion-symmetry breaking 3D Weyl semimetals of the TaAs family, primarily by ARPES (Yang et al., 2015; Xu et al., 2015b; Liu et al., 2016b). Predicted materials with a stable 3D Weyl semimetal phase of this family of compounds included TaAs, TaP, NbAs, and NbP. These materials belong to the class of type-I Weyl semimetals, which have point-like Fermi surfaces at the Weyl nodes. As shown in Fig. 9, surface Fermi arcs connecting pairs of 3D Weyl points projected onto the surface Brillouin zone and the linear energy-momentum dispersion of bulk states were systematically identified by extensive ARPES measurements (Yang et al., 2015; Xu et al., 2015b; Liu et al., 2016b). In addition to photon-energy-dependent ARPES, the surface and bulk character of the different states were confirmed by low-energy surface-sensitive ARPES and soft-X-ray bulk-sensitive ARPES, the latter of which enabled the observation of the 3D Weyl nodes in isolation.

One important aspect facilitating the experimental verification of topological order is the influence of increasing spin-orbit coupling strength on the electronic properties of these compounds. As seen in the comparison between ARPES measurements of the Fermi surface and band dispersions of NbP, TaP, and TaAs, shown in Fig. 9, increasing the spin-orbit strength increases both the separation between the Weyl nodes in momentum space and the splitting of the band dispersions, which causes a splitting of the Fermi arcs while retaining the overall topology of the Fermi surface (Liu et al., 2016b). While this observation by itself provides

(D) Zoom in on the region of the surface Fermi arcs where the positive and negative signs indicate the chiralities of the Weyl points. (E–G) Comparison of different pnictide Weyl semimetals. From NbP through TaAs, the splitting between the Weyl points and the length of the surface Fermi arcs increases. This splitting increases with the spin-orbit coupling (SOC). Panels (A–D) from Xu S-Y, Belopolski I, Alidoust N, Neupane M, Bian G, Zhang C, Sankar R, Chang G, Yuan Z, Le C-C, Huang S-M, Heng H, Ma J, Sanchez DS, Wang B, Bansil A, Chou F, Shibaev PP, Lin H, Jia S, and Hasan MZ (2015b) Science 349: 613–617 and (E–G) from Liu ZK, Yang LX, Sun Y, Zhang T, Peng H, Yang HF, Chen C, Zhang Y, Guo YF, Prabhakaran D, Schmidt M, Hussain Z, Mo S-K, Felser C, Yan B, and Chen YL (2016b) Nature Materials 15: 27.

additional evidence for the Weyl semimetal state, it also allows to experimentally identify groups of Weyl nodes with zero net chirality, establishing an independent criterion for the experimental verification of topological order.

By combination of bulk-sensitive soft-X-ray ARPES, spin resolution, and CDAD, it has been possible to observe large spin and orbital-angular-momentum polarizations in TaAs (Ünzelmann et al., 2021). From the winding of the orbital angular momentum, the Weyl points have been confirmed as Berry flux monopoles (Ünzelmann et al., 2021).

Type-II Weyl semimetals exhibit strongly tilted 3D Weyl cones in energy-momentum space, resulting in a Fermi surface where the upper and lower cones form electron and hole pockets that connect at the Weyl points. In consequence, type-II Weyl semimetals undergo peculiar Lifshitz transitions. The original prediction included the layered material WTe₂, known for its large, nonsaturating magnetoresistance, as well as MoTe₂ which we will discuss in Section “Weyl phases in inversion asymmetric TMDs.” Moreover, ARPES found also evidence for a type-II Weyl semimetal in TaIrTe₄ (Koepernik et al., 2016; Haubold et al., 2017) and LaAlGe (Xu et al., 2017b).

Magnetic Weyl semimetals and kagome systems

The alternate route towards the creation of topological Weyl semimetals from Dirac semimetals is to instead break time-reversal symmetry by the application of an external magnetic field or through a spontaneous magnetization. In the ferromagnetic Heusler compound Co₂MnGa, linear bulk band dispersions were observed, which intersect in a nodal line near the Fermi energy (Belopolski et al., 2019) and are spin polarized (Sumida et al., 2020). Another such crossing at higher binding energy is spanned by a surface state in the shape of a drumhead supporting the assignment of the system to a Weyl semimetal (Belopolski et al., 2019). YbMnBi₂ is a magnetic system with a canted antiferromagnetic structure. By comparison to the control system EuMnBi₂, Weyl points and a Fermi surface arc have been observed and the system was classified as time-reversal-symmetry breaking type-II Weyl semimetal (Borisenko et al., 2019).

Insulating kagome materials can exhibit spin liquid phases as a result of magnetic frustration. The same interferences determine the electronic structure, which is particularly interesting for metallic systems. With spin-orbit coupling and spontaneous magnetization, a two-dimensional kagome lattice leads to a 2D Chern insulator phase with quantized anomalous Hall conductance (Xu et al., 2015a). The resulting 2D Dirac cones have been observed by ARPES in Fe₃Sn₂ (with Fe₃Sn kagome layers between Sn layers) and in FeSn (Kang et al., 2020b). A gap in the 2D Dirac cone in Fe₃Sn₂ observed by ARPES has been assigned to spin-orbit interaction (Ye et al., 2018). Depending on the stacking of the kagome layers, the system can transform into a magnetic 3D Weyl semimetal. Co₃Sn₂S₂ consists of a Co₃Sn kagome layer and a S₂ honeycomb layer and was identified by ARPES as such a magnetic Weyl semimetal (Liu et al., 2019; Morali et al., 2019; Xu et al., 2018c).

The kagome magnet RMn₆Sn₆ with rare-earth element R, in which Mn forms the kagome layer, is promising for the realization of different quantum phases due to a variety of magnetic structures. In the system YMn₆Sn₆, a Dirac cone dispersion was seen by Li et al. (2021b). Another signature of the kagome lattice is a flat (i.e., minimally dispersive) band. Such a flat band is observed ≈0.25 eV below the Fermi level in FeSn (Kang et al., 2020b), and similar flat bands appear in paramagnetic CoSn near the Fermi energy (Liu et al., 2020; Kang et al., 2020a). These observations are interesting since a flat band on the kagome lattice carries a finite Chern number, enabling a fractional quantum Hall state.

Case study: Transition metal dichalcogenides

With time, it is becoming apparent that nontrivial band topology, along with Dirac and Weyl nodes, is far from contained to the handful of compounds within which the first examples were found. Conversely, topological band properties are ubiquitous, generic features of band structures found across nature. Indeed, computational studies tasked with scouring the electronic structures of all existing solids for nontrivial band topology predict that more than one quarter of all existing solids have an inverted band gap somewhere within their electronic structures (e.g., Vergniory et al., 2019).

No material family better exemplifies the plethora of topological phases only recently verified to exist in previously well-studied compounds than the TMDs, a materials family exhibiting numerous examples of nontrivial band topology, bulk Dirac points, and Weyl points, often simultaneously, and alongside many other desirable properties for next-generation device fabrication. The TMDs are a family of >30 stable compounds with the formula MX₂, where M is a transition metal and X ∈ {S, Se, Te}. Each of these van der Waals layered materials stabilizes in one or more of the following structures: 1T (P3̄m1), 2H (P6₃/mmc), 3R (R3m) or in one of several distorted trigonal structures (triclinic ($\bar{P}1$), monoclinic (β , P2₁/m) and orthorhombic (γ , Pmn2₁)), here collectively referred to as 1T'. A subset of these is schematized on the left hand side of Fig. 10 (Chen et al., 2021).

The thermodynamically favored structural phase of a TMD defines the crystal field splitting of the transition metal *d*-orbital manifold, which, together with the electron filling factor, determines many of the ground-state electronic properties of the TMDs (Chhowalla et al., 2013). For 2H (and 3R) structured TMDs (*D*_{3h}), the *d*-orbital manifold is split into three energetically separated subsets (*a*₁, *e*, and *e'* from low energy to high) located between the bonding and antibonding chalcogen *p*-orbital manifolds and are found predominantly in groups V (*d*¹ metals) and VI (*d*² semiconductors). 1T- and 1T'-structured TMDs instead have the *d*-orbital manifold split in two (*t*_{2g} and *e*_g) with examples found in groups IV (1T *d*⁰ semiconductors), V (1T *d*¹ metals), VI (1T' (monoclinic/orthorhombic) *d*² metals), VII (1T' (triclinic) *d*³ metals), IX (1T *d*⁵ metals), and X (1T *d*⁶ (semi)metals). For the latter two cases, M-M bonds are preferentially formed over M-X bonds, placing the Fermi level within the antibonding *p*-orbital manifold. Both 1T and 2H

d^1 metallic systems contain charge density instabilities, with the signatures of back-folded bands clearly seen by several spectroscopic techniques including ARPES (Ritschel et al., 2015; Rosnagel et al., 2005; Wang et al., 2021b; Feng et al., 2018; Chen et al., 2022; Nakata et al., 2021; Borisenko et al., 2009; Terashima et al., 2003). These phases are often precursors to superconductivity at low temperatures (Koley et al., 2020; Xi et al., 2016; Liu et al., 2016a; Sahoo et al., 2020), a property also shared by many of the metallic d^5 and d^6 TMDs (Park et al., 2021; Zheng et al., 2020; Ryu, 2015). Perhaps most famously, the d^2 2H semiconductors are the central focus of the burgeoning field of valleytronics owing to their graphene-like honeycomb lattice structure (Fig. 10) and thus their layer and momentum-locked Rashba-split valence band maxima (see e.g., the seminal photoluminescence studies Mak et al., 2010 and Xiao et al., 2012).

The topological properties of these materials only began to draw attention in 2015 with the prediction and subsequent verification of type-II Weyl nodes and Fermi arcs in the d^2 1T' (orthorhombic, γ)-structured tellurides, MoTe_2 and WTe_2 (see the review by Das et al., 2019), establishing the TMD family as among the first hosts of type-II Weyl semimetals. In addition to this wide array of TMD properties deriving primarily from the transition metal d -orbital manifold, remarkably, the 1T and 2H TMDs were additionally found to host TSSs and/or bulk Dirac points, the hallmarks of TIs and Dirac semimetals, respectively. In contrast to the Weyl phases of the 1T'-TMD subset, these topological properties stem entirely from within the chalcogen p -orbital manifold and are thus largely insensitive to the choice of the transition metal (Bahramy et al., 2018). Nontrivial band topology and/or bulk Dirac crossing points can therefore be found across the entire 1T and 2H TMD subclasses. Already, the topologically nontrivial TMDs have been shown to be of practical interest, with “giant” or nonsaturating magnetoresistance observed in both TMD Dirac and Weyl semimetals (see e.g., Ali et al., 2014b; Pavlosiuk and Kaczorowski, 2018), and tunable, high-efficiency THz detection realized in numerous group-X Dirac semimetals (e.g., Cheng et al., 2023; Guo et al., 2020).

The type of the protected crossings available to each TMD compound (2D Dirac, 3D Dirac or Weyl) is determined only by whether an axis of rotational symmetry and/or an inversion center is present within the crystal structure. In the 1T- and 2H-structured TMDs, the C_{3v} -symmetric k_z axis is capable of protecting any formed bulk Dirac points against perturbations including spin–orbit coupling (Yang and Nagaosa, 2014). By lifting inversion (or time-reversal) symmetry in such a way that the rotational axis is preserved, Dirac nodes could be transformed into Weyl points in the usual way. In contrast, the 1T' (γ) structured TMDs possess neither a sufficient rotational axis nor inversion symmetry. In this scenario, Weyl points can be instead formed at the intersection of electron- and hole-like states at low symmetry k -vectors and are unrelated to the Dirac points in their 1T-structured counterparts. These two cases will be briefly overviewed below.

Dirac cones in inversion symmetric TMDs

The mechanism underpinning the simultaneous formation of bulk Dirac points and TSSs in bulk 1T and 2H structured TMDs has been extensively discussed in Bahramy et al. (2018) and Clark et al. (2019), thus explaining the preexisting observations of a TSS in PdTe_2 (Liu et al., 2015), and bulk Dirac points in PtTe_2 (Yan et al., 2017) and PtSe_2 (Huang et al., 2016a). This mechanism, applied to a 1T-TMD crystal structure, is schematized in Fig. 10 (Clark et al., 2019). In short, the bonding (B) and antibonding (AB) sets of

the chalcogen p -orbitals are each split into three doubly degenerate bands by the combined influence of the trigonal (C_{3v}) crystal field and the spin-orbit interaction: The p_z -derived R_4 and the $p_{x,y}$ -derived R'_4 and R_5 , where the subscript denotes the irreducible representation. In van der Waals stacked systems, out-of-plane hopping across the van der Waals gap is in general larger for p_z orbitals due to the larger spatial extent into the gap. The out-of-plane bandwidth ($\propto k_z$) of p_z -derived bands in momentum space is therefore larger than that of the pair of $p_{x,y}$ -derived bands, making crossings between the six p -derived bands along k_z (3 for each AB and B sets) highly likely. Around half of these crossings will be between bands of different irreducible representations, producing C_{3v} lattice symmetry protected bulk Dirac points (Yang and Nagaosa, 2014). The rest will hybridize to open up band gaps, which may be topologically nontrivial depending on the parity of the involved bands, which in real TMD systems typically correlates with the sign of group velocity of each band between the Γ and A high-symmetry points. The result is a ladder of 3D and 2D Dirac cones, centered at the $\bar{\Gamma}$ point of the surface Brillouin zone and stacked along the energy axis.

The bulk Dirac points produced by this mechanism occur at low symmetry k points between Γ and A and, as a result, typically exhibit anisotropic band dispersions in three dimensions, thus violating the Lorentz symmetry intrinsic to the Dirac fermion analogs in high energy physics. Instead, their dispersion is tilted, with the type of Dirac cone determined by whether the two branches of the cone have different (type-I) or the same (type-II) sign of the group velocity in analogy to the tilted Weyl cones of type-II Weyl semimetals.

Clear ARPES and/or density functional theory evidence for topological ladders has been reported in the 1T systems PdTe₂ (Liu et al., 2015; Noh et al., 2017; Bahramy et al., 2018; Clark et al., 2018, 2019), PtTe₂ (Yan et al., 2017), PtSe₂ (Huang et al., 2016a; Bahramy et al., 2018), NiTe₂ (Xu et al., 2018a; Ghosh et al., 2019; Mukherjee et al., 2020; Nurmamat et al., 2021), CrTe₂ (Ou et al., 2022; Li et al., 2021c), HfSe₂ (Clark et al., 2022), CoTe₂ (Chakraborty et al., 2023), and IrTe₂ (Bahramy et al., 2018; Fei et al., 2018; Jiang et al., 2020; Nicholson et al., 2021). The differences in the composition of the topological ladder depend largely on the starting energetics of the six doubly degenerate p -derived bands: a combination of the B-AB splitting (determined by the degree of orbital overlap), the crystal field strength, and the chalcogen spin-orbit coupling strength. For example, in PdTe₂ (Fig. 11A–C Bahramy et al., 2018; Clark et al., 2018), the bandwidth of the p_z -derived AB- R_4 band is large enough to cross through both the

Fig. 11 Topological ladders in bulk transition metal dichalcogenides. Compilation of ARPES and spin-resolved ARPES findings on (A–C) 1T-PdTe₂ (Clark et al., 2018; Bahramy et al., 2018), (D–G) 2H-WSe₂ (Bahramy et al., 2018), (H) 1T-NiTe₂ (Mukherjee et al., 2020) and (I,J) 1T-HfSe₂ (Clark et al., 2022). Orbital-projected density functional calculations in (A,D,E) share the color bar inset on the left, though the transition metal d -orbital contribution is neglected in (A). Calculations in (D) are zoom-ins of the indicated regions in (E). Circular dichroic spectrum in (F) is a zoom-in of the TSS region in (G) to better resolve the TSS. Highlighted (black box) region in (C) is performed with a higher photon energy to optimize matrix elements of TSS1. Highlighted regions in (G) and (H) have an increased image contrast only. Dashed lines in (C) and (F) indicate the energy ranges and approximate momentum positions for the spin-resolved energy and momentum distribution curves in (B) and (F), respectively (refer to original publications for details). Inverted band gaps (IBGs), trivial hybridization gaps (HG), Type-I/II bulk Dirac points (BDPs (I/II)), and topological surface states (TSSs) are labeled throughout. AB and B sets of $p_{x,y}$ -derived bands as well as the oppositely dispersing B- R_4 band, thus creating a total of two bulk Dirac points and three TSSs at $\bar{\Gamma}$. In contrast, in HfSe_2 (Fig. 11I,J; Clark et al., 2022), the smaller chalcogen and larger van der Waals spacing lead to a much reduced bandwidth of the p_z -derived bands and no overlap between the B- and AB-derived p -orbital manifolds. The result is a topologically trivial hybridization gap and a single type-II bulk Dirac cone formed along $\bar{\Gamma}$ -A within the p -orbital manifold, though it is particularly noteworthy that the pair of type-II bulk Dirac points (symmetric about A) comprises the valence band maximum of this compound (Clark et al., 2022).

Although typically buried deep within the valence bands due to the energetic positioning of the chalcogen manifold, similar physics was found in the 2H-structured TMDs WSe_2 , NbSe_2 , and TaSe_2 (Bahramy et al., 2018). The 2H-structured variants have an extra consideration: by doubling the size of the unit cell along the c -axis, the number of distinct p -derived bands also doubles, thus providing twice the opportunities for bulk Dirac point and inverted band gap formation. For example, in 2H- WSe_2 , pairs of very closely spaced (in energy and momentum) inverted band gaps and bulk Dirac points (which are necessarily of opposite types due to opposite group velocity of the two halves of a back folded $p_{x,y}$ -derived band) are predicted by density functional theory, with a TSS verified by spin-resolved ARPES (Bahramy et al., 2018), see Fig. 11D–G. The observable surface state has its dispersion heavily influenced by the restricting nature of the surrounding small k_z -projected band gap to produce a Rashba-like dispersion. This is a common phenomenon across these materials, with both trivial and TSSs adopting highly usual dispersions due to the presence of only narrow channels left unexplored by the bulk electronic structure. This is particularly clear in PdTe_2 (Clark et al., 2018, 2019) and NiTe_2 (Mukherjee et al., 2020), where an inverted band gap above the Fermi level spawns a topological state with a dispersion maximally warped by the dense k_z -projected bulk manifold, eventually crossing the Fermi level along $\bar{\Gamma}$ - $\bar{M}$ (Fig. 11C,H) with a highly complex in-plane spin texture (Clark et al., 2018; Mukherjee et al., 2020).

In conjunction with the Weyl semimetals within the TMD family, the surface and bulk Dirac physics of the rotationally symmetric subclass establishes the TMDs as an ideal platform to study all types of topological band structure, and their interplay with other material-specific properties. It is noteworthy that the generality of topological ladders to the rotationally symmetric material class as a whole is a direct consequence of the single-orbital manifold nature of the various band inversions contained within, and demonstrates an insensitivity of this nontrivial band topology to changes in spin-orbit coupling strength, d -orbital manifold overlap, and unit cell size. This is in sharp contrast to systems with band inversions between two distinct orbital manifolds, for example in the Bi_2Se_3 series, wherein the band inversions can be unwound by sufficiently altering the energetic separation of the Bi p and Se p -orbital manifolds, for example, through reducing the spin-orbit coupling strength.

Despite the robustness of the topological phases, the composition and energetics of the topological ladders in TMDs have been shown theoretically to be highly tunable through any perturbation altering the relative hopping parameters within the chalcogen sublattice, such as through alloying or through strain/compression (Bahramy et al., 2018; Huang et al., 2016a; Xiao et al., 2017; Clark et al., 2019). Of particular interest experimentally is the case of IrTe_2 , which possesses a type-II bulk Dirac cone 100 meV above the Fermi level as well as two inverted band gaps located at higher binding energy (Bahramy et al., 2018; Fang et al., 2013; Nicholson et al., 2021). Tantalizingly, this compound also undergoes several temperature-driven structural phase transitions from 280 K, eventually finding a 6×1 ground state (see Nicholson et al., 2021 and references within). While the ground state typically has nanoscale domain sizes, the application of 0.1% strain along the a -axis stabilizes this 6×1 phase sufficiently to probe in isolation with ARPES.

In principle, this change of symmetry should lift the protection of the bulk Dirac points due to the loss of C_{3v} rotational symmetry, suggesting the possibility to exploit the structural transition as a temperature-controlled switch for bulk Dirac transport in this compound (Yang and Nagaosa, 2014). In contrast, it was not only observed that some signatures of the bulk Dirac point seem to endure this breaking of symmetry, but also that the energetics of the Dirac node fall below E_F in the 6×1 phase and become the dominant interlayer transport channel (Nicholson et al., 2021). This temperature-controlled Lifshitz transition is accompanied by the corresponding nonsaturating linear magnetoresistance (Zhang et al., 2019b). Alternatively, a similar Lifshitz transition can be achieved in the high-temperature trigonal structure by doping with Pt (Fei et al., 2018; Jiang et al., 2020), which remains superconducting for Pt concentrations < 0.4 , a range that includes the composition where the bulk Dirac point is at E_F (Fei et al., 2018; Jiang et al., 2020). These studies provide a proof of principle for tunable topological phases in TMDs in general, and highlight the ever-growing phase space available for *in situ* manipulation of electronic structures with ARPES.

This single-orbital manifold origin responsible for both the robustness and tunability of these Dirac nodes is not limited to the TMD family. Prior predictions of type-II bulk Dirac points near the Fermi level in both the VAL_3 (Chang et al., 2017b) and YPd_2Sn (Guo et al., 2017) families can be understood within this same framework, with the bulk Dirac points protected by fourfold rotational symmetries in analogy to the threefold symmetry-protected Dirac crossings in the TMDs. More recently, PdTe , like PdTe_2 , was found to host a series of p -orbital derived band crossings along the $\bar{\Gamma}$ -A direction of its $\text{P6}_3/\text{mmc}$ -type Brillouin zone by ARPES (Yang et al., 2023). While the presence of only one chalcogen per unit cell precludes any topologically nontrivial hybridization gaps within the p -orbital manifold, a type-I bulk Dirac point is formed within 100 meV of E_F . Crucially, unlike in the dichalcogenides, there is a possibility to realize a surface termination wherein pairs of bulk Dirac points formed along A- $\bar{\Gamma}$ -A do not project to the same point in the surface Brillouin zone, enabling the experimental characterization of Fermi arcs spanning between bulk Dirac points.

Weyl phases in inversion asymmetric TMDs

The first examples of topological phases found in the TMDs were the cases of the distorted type-II Weyl semimetals γ - WTe_2 and γ - MoTe_2 introduced in Section “Nonmagnetic Weyl semimetals.” Despite being the first topological phases predicted in the TMDs,

the experimental verification proved much more challenging than that of the Dirac phases inherent to the inversion symmetric TMDs. Where the topological ladders in, for example, the group-X TMDs are ideal for direct observation in ARPES due to the large energy and momentum scales involved, the Weyl nodes in MoTe_2 and WTe_2 occur at low symmetry points between electron and hole pockets, which disperse almost parallel to each other in the vicinity of the produced type-II Weyl points, thus leaving energetically narrow channels for Fermi arcs to disperse at all relevant k -points. Moreover, these crossings, protected by time-reversal symmetry, are located above the Fermi level, which precludes imaging them directly with conventional ARPES (Soluyanov et al., 2015; Das et al., 2019). This, combined with multiple surface terminations, the presence of trivial surface states alongside the predicted Fermi arcs (Bruno et al., 2016) and a perceived extreme sensitivity of the Weyl nodes to strain and pressure (Soluyanov et al., 2015; Bruno et al., 2016), made an unambiguous classification of bulk MoTe_2 and WTe_2 and a complete mapping of Fermi arc spin textures difficult by purely spectroscopic means (Das et al., 2019). Nevertheless, there is now significant spectroscopic evidence for Fermi arc surface states (and thus type-II Weyl points) in these compounds (Wu et al., 2016b; Wang, 2016; Sánchez-Barriga et al., 2016b; Bruno et al., 2016; Tamai et al., 2016; Jiang et al., 2017; Xu et al., 2018b; Huang et al., 2016b; Wan et al., 2022), with further evidence from transport experiments consistent with the presence of type-II Weyl points (Hosur and Qi, 2013; Udagawa and Bergholtz, 2016; Li et al., 2017). In addition, both of these compounds have been shown to be highly tunable. For example, the extremely large magnetoresistance in WTe_2 , originating from a perfect compensation of charge carriers (Ali et al., 2014b; Alekseev et al., 2012; Das et al., 2019), is significantly amended following Lifshitz transitions that can be driven with temperature (Wu et al., 2015; Pletikosić et al., 2014) or pressure (Kang et al., 2015). In MoTe_2 , a structural transition from the orthorhombic (γ) Weyl semimetal phase into the monoclinic (β) phase occurs above 240 K (Xu et al., 2018b; He et al., 2018). This transition restores the inversion symmetry inherent to the undistorted 1T phase into the system, but not the threefold rotational symmetry. This combination thus precludes the presence of the type-II Weyl nodes found in the γ phase as well as the bulk Dirac nodes of the kind found across the 1T-TMDs (Yang and Nagaosa, 2014). The compound remains interesting for its topological properties, however, as β -type 1T'-TMDs are theoretically predicted to contain higher order nontrivial band topology (Tang et al., 2019; Wang et al., 2019). This same γ - β transition can be induced in 1T'- WTe_2 with ultrafast THz radiation (Sie et al., 2019).

In addition to the Weyl physics in the 1T' TMDs, each bulk Dirac point in the 1T and 2H TMDs has the capacity to have its degeneracy reduced by breaking time-reversal or inversion symmetries, so long as the underpinning C_3 symmetry remains intact. While this has not yet been shown explicitly, this could be achieved by lifting time-reversal symmetry through the application of external magnetic fields or through the inclusion of magnetic dopants. Similarly, 1T- CrTe_2 may possess Weyl points intrinsically due to the combination of magnetic ground state (see, for example, Freitas et al., 2015; Zhang et al., 2021 for bulk and thin film variants) and a chalcogen p -orbital manifold, which is likely to share the k_z -mediated band inversions of its sister compounds. Alternatively, inversion symmetry can be explicitly broken through the fabrication of artificial TMD structures with inequivalent top and bottom chalcogen sublayers, such as in the so-called "Janus" TMDs ($X_1\text{-M-X}_2$, $X_1 \neq X_2$), although this is not necessarily a sufficient criterion to form Weyl nodes, with Dirac (fourfold) and triple (threefold) degenerate points maintained or formed in density functional theory studies of bulk Janus TMDs (Xiao et al., 2018; Bahramy et al., 2018). The creation of bulk Janus TMDs remains largely theoretical due to the logistics of such a precise sample growth (Yin et al., 2021; Griffith et al., 2023), though monolayer Janus TMDs in 1H, 1T, and 1T' structures have been successfully synthesized (Tang and Kuo, 2022; Li et al., 2018a; Zhang et al., 2017; Trivendi et al., 2020; Zheng et al., 2022; Gan et al., 2022) but have yet to be measured by ARPES.

Thin limit

While bulk TMDs offer a rich platform in which to study and induce a wide array of novel physics, next-generation electronic or spintronic devices harnessing TMD materials are likely to turn to their few-layer variants both for easier control through gating (Nguyen et al., 2019b; Lei et al., 2022) and for optimized integration with other materials (Ji and Choi, 2022; Pham et al., 2022). Fortunately, the van der Waals nature of TMD systems makes them ideal for epitaxial growth via MBE on a wide array of substrates, including graphene, which is both highly conducting and largely inert (see e.g. the following ARPES studies: Zhang et al. (2021), Ou et al. (2022), Coelho et al. (2019), Feng et al. (2018), Biswas et al. (2021), Dreher et al. (2012), Watson et al. (2021), and Antonelli et al. (2022)). Similarly, numerous methods of mechanically exfoliating monolayers from bulk single crystals are possible, rendering high quality films, which can be integrated into devices, though the size of such films is typically on the order of 20 μm . The development of nano-ARPES (i.e., ARPES with focused light spots smaller than 1 μm) and angle-resolved photoelectron emission microscope (PEEM) beamlines worldwide has therefore proven crucial for the systematic characterization of these exfoliated TMD flakes and their devices (Grubisic-Cabo et al., 2023; Stansbury et al., 2021; Pei et al., 2022; Khalil et al., 2023; Nguyen et al., 2019b; Jones et al., 2022), and for TMD thin films more generally which are often spatially inhomogeneous and suffer from rotational disorder. Moreover, MBE grown or exfoliated TMD flakes can be capped with amorphous Se and/or Te to prevent film degradation between growth chamber and ARPES ultra-high vacuum environments, or often simply annealed *in situ* without prior capping to remove surface contaminants.

For the 1T'-structured TMDs, thinning MoTe_2 down to the few layer limit (less than 12 nm) has been found to remove the structural transition to the inversion-symmetric monoclinic phase, thus providing access to the type-II Weyl nodes, usually found only within the low-temperature inversion asymmetric orthorhombic (γ) phase, at room temperature (He et al., 2018). In the single-layer limit, both MoTe_2 and WTe_2 become inversion symmetric (though inversion symmetry is removed with a small perpendicular electric field) since the β and γ phases differ only by their stacking pattern along the c -axis, and are therefore equivalent in the single layer (Rhodes et al., 2021; Shi et al., 2019). While a 2D analog of Weyl nodes may then not be expected, monolayer 1T'- WTe_2 has been shown to be an intrinsic two-dimensional TI via numerous experimental methods including

Fig. 12 Tunable topological phases in bulk and thin-film TMDs. (A–C) Temperature- and strain-dependent ARPES results on 1T–IrTe₂. (D,E) Band structure calculations and ARPES spectrum of (*n*-doped) monolayer 1T′–WTe₂. (F) Thickness-dependent ARPES of PtTe₂ thin films. ARPES (Fig. 12E), with inverted band gaps formed within the *d*-orbital manifold near the Fermi level generating topologically protected, conductive spin-polarized edge states around the perimeter of the semiconducting film (Tang et al., 2017c; Fei et al., 2017; Shi et al., 2019; Zhao et al., 2021).

For the 1T, and 2H-structured TMDs, one would not expect topological ladders of bulk and surface Dirac nodes to survive the thinning down to a single monolayer. Their formation, along the *k_z*-axis, relies on the intra- and interlayer hopping channels perpendicular to the surface plane, which are strongly reduced in the few layer limit. Indeed, no pristine monolayer TMDs have been found to host any Dirac nodes. For example, in its bulk 1T–PtTe₂ is metallic and hosts two bulk Dirac cones and three inverted band gaps at $\bar{\Gamma}$ (Yan et al., 2017). In its monolayer, it is a topologically trivial semimetal (Deng et al., 2019). However, the topological physics reappears abruptly as soon as 4 monolayers are reached, with clear TSS and “bulk” Dirac states observed by ARPES in MBE grown films (Fig. 12F) (Deng et al., 2019). A similar phenomenon was observed in semimetallic NiTe₂ films, where gapless TSS are found in five-layer samples, alongside conical bands deriving from the (near-*E_F*) type-II bulk Dirac cone in the bulk limit (Fig. 12G, H; Hlevyack et al., 2021). These studies suggest that the topological crossing points are not gradually unwound with reduced thickness, but rather that the hierarchy of band inversions is left intact along a discretized *k_z*-axis. The layer number needs only be sufficient to (a) access *k_z* sub-bands where bulk Dirac points form, and/or (b) access subbands on the nontrivial side of the *k_z*-mediated topological phase transitions which generate the surface Dirac nodes. As with all TIs, the film needs also to be sufficiently thick to avoid wavefunction interference of TSSs on opposing surfaces. Topological phases may also be induced in monolayer 1T-TMDs via chemical substitution. For example, in monolayer 1T–PtSe₂, a 2D topological insulating phase, unrelated to nontrivial band topology of the bulk, has been theoretically shown to be induced through Se–Hg substitution (with one nontrivial alloy naturally occurring), with the resulting topologically nontrivial edge states crossing the Fermi level (Craeto de Lima et al., 2023).

Altogether, the presence of both bulk Dirac nodes and nontrivial topology in the few-layer TMD limit opens avenues to incorporate topological physics in thin film heterostructures. For example, designer topological ladders, with selective control over the numbers, types, and energetics of Dirac nodes, may be engineered in 1T and 2H TMD heterostructures with a careful choice of TMD on a layer-by-layer basis. Such heterostructures could also open routes to drive correlated topological phases not possible in the bulk systems. In analogy to the induction of Mott gaps and superconductivity in bilayer graphene through the delicate control of the relative twist angle between the two monolayers (Cao et al., 2018), it has been shown how correlated phases are achievable in both twisted heterobilayer and homobilayer TMDs. In short, the moiré superlattice potential defined by the lattice mismatch between constituent layers enables hybridization channels between states that were previously well separated in momentum space, due to extreme back-folding into the reconstructed “mini” Brillouin zone. This produces flat bands from which correlated phases can emerge with the right band filling. Such flat bands have already been observed spectroscopically for numerous TMD heterostructures (Stansbury et al., 2021; Pei et al., 2022; Li et al., 2021a), with a correlated insulator phase experimentally found at half-band filling (Wang et al., 2020). While such findings already allude to technological applications such as the Mott field effect transistor, the coexistence of nontrivial band topology and these engineered correlated phases is yet to be explored, but is in reach, as demonstrated by the presence of topological states in monolayer WTe_2 (Tang et al., 2017c), monolayer $\text{PtHg}_{1-x}\text{Se}_{2-x}$ (Craeto de Lima et al., 2023) and 4–5 layer PtTe_2 (Deng et al., 2019) and NiTe_2 (Hlevyack et al., 2021).

Topological nodal-line semimetals

In analogy to the zero-dimensional nodes discussed in the previous sections, it is possible to produce one dimensional nodal lines along complete k -paths through a Brillouin zone (schematized in Fig. 13A). The hosting compounds, Dirac nodal line semimetals, often require additional crystalline symmetries with respect to Dirac and Weyl semimetals to ensure the protection of Dirac degeneracies over extended k -paths, at least in the absence of spin–orbit coupling. These nodal lines can take the form of nodal rings, chains, links, and knots (Kim et al., 2015; Fang et al., 2015; Bzdušek et al., 2016; Bi et al., 2017; Fu et al., 2019) and, while the nodal line stays ungapped (neglecting spin–orbit coupling) over the full momentum range, the Dirac node is free to move in energy. By now, many examples of nodal line semimetals have been theoretically predicted and/or experimentally confirmed with ARPES, including Mg_3Bi_2 (Chang et al., 2019), which possesses nodal lines only in the absence of spin–orbit coupling due to the presence of only time reversal and inversion symmetries, and PbTaSe_2 (Bian et al., 2016), Cu_3PdN (Yu et al., 2015), Ca_3P_2 (Xie et al., 2015), the CaP_3 family (Xu et al., 2017a), and EuAs_3 (Cheng et al., 2021), which host nodal lines protected in the absence of spin–orbit coupling due to reflection/mirror symmetries, and occasionally in the presence of spin–orbit coupling (TaPbSe_2), depending on the Brillouin zone path where the nodal line occurs and the presence of inversion symmetry. It is noteworthy that the addition of spin–orbit coupling transforms a subset of these compounds into Dirac semimetals with lattice-symmetry protected bulk Dirac points (Yu et al., 2015).

Dirac points and Dirac nodal lines are overlaid with red markers/lines. Other colorings indicate orbital character. (C) k_z integrated band structure calculations demonstrating the energy dispersion of the nodal line. (D) k_z -dependent datasets and overlaid band structure calculations demonstrating the continued presence of a protected Dirac crossing along the k_z path. (E) Crystal structure of nonsymmorphic ZrSiS. (F) Band structure calculations, (G) ARPES dispersions, and (H) ARPES Fermi surfaces of ZrSiS, for surface (left) and bulk (right) derived electronic structures. Yellow squares in (H) indicate the surface (bulk) Brillouin zones with the $\bar{M}$ (M) and $\bar{X}$ (X) points on the corners and edges, respectively. Adapted from (A–D) Ekahana SA, et al. (2017) New Journal of Physics 19: 065007; (E) Pezzini S, et al. (2018) Nature Physics 14: 178–183; and (F–H) Fu B-B, et al. (2019) Science Advances 5(5): auu6459.

There are instances where the nodal lines are resilient to spin–orbit coupling gapping along extended k -paths, however. These cases employ nonsymmorphic symmetry: a combination of a fractional lattice symmetry and either a glide plane or screw axis (Wu et al., 2022; Wang et al., 2016b; Yang et al., 2018). Nonsymmorphic compounds with nodal lines include InBi (Fig. 13B–D) (Ekahana et al., 2017), $\text{Pt}(\text{Sn}, \text{Pb})_4$ (Wu et al., 2016a, 2022), and $(\text{Ta}, \text{Nb})_3\text{SiTe}_6$ (Li et al., 2018b). Perhaps most extensively studied, however, is the Matlockite ($P4/nmm$) materials family, M_1M_2X , where $M_1 \in \{\text{Zr}, \text{Hf}, \text{La}, \text{Na}\}$, $M_2 \in \{\text{Sb}, \text{Ge}, \text{Si}\}$, and $X \in \{\text{S}, \text{Se}, \text{Te}\}$, which have been extensively characterized by ARPES (Schoop et al., 2016; Neupane et al., 2016; Chen et al., 2017; Topp et al., 2017; Hosen et al., 2017; Wang et al., 2016a; Yen et al., 2021; Cheng et al., 2019; Fu et al., 2019; Wang et al., 2021a; Lou et al., 2016). These compounds contain zero-dimensional Dirac nodes protected by the nonsymmorphic symmetry itself, which here results from a glide-mirror symmetry with respect to the Si layer in ZrSiS for example (Fig. 13E), and one-dimensional nodal lines protected by the combination of inversion and time-reversal symmetries (Schoop et al., 2016). The latter continuously connect Dirac crossings found along the high-symmetry $X\text{--}\Gamma$ and $\Gamma\text{--}M$ directions to form a line of Dirac degeneracies along low-symmetry paths near the Fermi level (Fig. 13F). The nodal line itself is not protected against spin–orbit coupling (unlike the nonsymmorphic symmetry protected Dirac nodes at higher binding energies), but in the case of ZrSiS, the small spin–orbit coupling strength renders only millivolt scale bandgaps (Fu et al., 2019; Yang et al., 2021). Note that this is different to the case of InBi (Fig. 13C and D), where the nonsymmorphic symmetry does fully protect the nodal lines even in the presence of strong spin–orbit coupling. More recently, it was predicted (Topp et al., 2017) and subsequently confirmed (Fu et al., 2019) that the nodal lines in ZrSiS form part of a nodal surface on the $k_z = 0$ and π contours of the Brillouin zone to produce a square-shaped bulk Fermi surface composed only of the near-Dirac degeneracies (Fig. 13G,H).

It is noteworthy that these systems host particularly rich surface electronic structures where the nonsymmorphic symmetries are broken. Indeed, in the ZrSiS family, the natural cleavage plane is between the Si layers, resulting in surface-derived “floating” pockets at the $\bar{X}$ point of the surface Brillouin zone, which accompany the Dirac nodal surface (Schoop et al., 2016; Topp et al., 2017; Fu et al., 2019; Yang et al., 2021), see Fig. 13F–H. These surface electronic structures can have rich properties of their own, including the formation of mirror-symmetry-protected crossings between pairs of Rashba-split surface states, which behave as 2D analogs of Weyl points (Marković et al., 2019).

Topological chiral semimetals

Chiral crystals are described by the 65 Sohncke space groups that contain only symmetry operations of the first kind (rotations and screwings), that is, they lack inversion, mirror, and roto-inversion symmetry. These have been suggested to host multifold fermions, which go beyond the Weyl, Dirac, and Majorana fermions of quantum field theory and of which the Weyl fermion is itself chiral. The discovered multiple degeneracies include three-, six-, and eight-band crossings stabilized by space group symmetries with spin–orbit coupling and time-reversal symmetry (Bradlyn et al., 2016).

The low-energy effective Hamiltonian describing, for example, the threefold crossing is a fermionic generalization of the Weyl Hamiltonian $H = \mathbf{k} \cdot \mathbf{S}$, where $\mathbf{k}$ is the momentum and the matrices S_i are the generators of the rotation group $SO(3)$ in the spin-1 representation. The bands of the multifold fermions bear a higher Chern number, ± 2 in the case of the threefold crossing, and also host a larger number of topologically protected surface Fermi arcs. The threefold fermions are predicted to show an anomalous negative magnetoresistance and a chiral anomaly different from that of single or double Weyl points. At large magnetic fields, the Landau-level spectrum displays two chiral modes with unusual momentum dependence (Bradlyn et al., 2016).

Threefold crossings have been observed before in MoP (Lv et al., 2017) and WC (Ma et al., 2018). Those, however, result from band inversion, and do not lead to defined Chern numbers. The multifold fermions, instead, do not require band inversion and occur at time-reversal invariant momenta. In contrast to Weyl fermions, they cannot move and annihilate and are therefore more robust as long as the relevant crystal symmetries are preserved. Single crossings of spin–orbit-coupled bands at time-reversal invariant momenta have been named Kramers–Weyl fermions (Chang et al., 2018).

In the presence of time-reversal symmetry, multifold fermions occur for several space groups. Among these groups, $P2_13$ (number 198) corresponds to a simple-cubic lattice where the sixfold degeneracy occurs at the R point (corner of the Brillouin zone) (Bradlyn et al., 2016). Space group 198 has been of particular interest because simple binary crystals are available such as transition metal monosilicides, monogermanides, monoaluminides, and monostannides. Specific predictions have been made, for example, for silicides (Tang et al., 2017; Chang et al., 2017a; Pshenay-Severin et al., 2018).

ARPES data have simultaneously been reported for PtAl (Schröter et al., 2019), CoSi (Rao et al., 2019; Takane et al., 2019; Sanchez et al., 2019), and RhSi (Sanchez et al., 2019). The associated large Chern numbers lead to multiple Fermi arcs. The chirality of the crystal structure can be deduced from the Fermi arc. Fig. 14A shows the comparison of the Weyl and Dirac fermion and multiple fermions: the chiral spin-1 fermion and the chiral double Weyl or charge-2 fermion. Fermi arcs span the surface projection of the high symmetry points at which the multifermions occur and, therefore, can span the whole surface Brillouin zone, depending on the surface. They are hence typically an order of magnitude longer than in Weyl semimetals, shown as sketch in Fig. 14B, and this is observed in ARPES (Schröter et al., 2019; Rao et al., 2019; Takane et al., 2019; Sanchez et al., 2019). For CoSi, a spin-1 fermion occurs at Γ (probed at soft-X-ray energies in Fig. 14F) and double Weyl fermions at the R points. The surface Fermi arcs span the whole (100) surface Brillouin zone from $\bar{\Gamma}$ to $\bar{M}$, see Fig. 14G,H). Their ARPES signature is independent of the photon energy due to their two-dimensionality (blue crosses 75 eV and red circles 110 eV in Fig. 14H).

Fig. 14 Multifold fermions in topological chiral semimetals CoSi, PtAl, PdGa, and PtGa. (A) Examples of multifold fermions as compared to Weyl and Dirac fermions. (B) Since they are located at time-reversal invariant momenta, the surface Fermi arcs extend across the complete surface Brillouin zone (left), in contrast to the case of Weyl semimetals (right). (C–H) CoSi with (C) crystal structure, (D) bulk and surface Brillouin zone, and (E) band structure. (F) Bulk-sensitive ARPES data (355 eV) of the spin-1 chiral fermion. (G,H) Surface fermi arcs from data at two different photon energies (75 and 110 eV) superimposed on the calculated bulk Fermi surface. (I) In PtAl the large spin-orbit splitting of ~ 100 meV can be resolved. (J,K) Likewise, the surface Fermi arc of PdGa is split. (L) Spin texture of a multifold fermion. (M,N) Measurements of the spin texture of the surface Fermi arc of PtGa allow conclusions on parallel spin-momentum locking of the bulk multifold fermion. For chiral semimetals with light elements, the spin-orbit splitting is small and not resolvable in ARPES. For PtAl, PdGa, and PtGa the spin-orbit coupling is, however, high and the splitting can be resolved in the bulk crossing of PtAl in Fig. 14I (Schröter et al., 2019) and in the Fermi surface arc of PdGa in Fig. 14J,K (Schröter et al., 2020). The splitting of the surface Fermi arc implies that four arcs connect the projections of the multifold fermions, which is consistent with them having a large Chern number with magnitude 4.

Topological chiral semimetals display a peculiar spin texture. We note that in Rashba systems, the presence of mirror symmetries render the spin perpendicular to the mirror plane for states with wave vector in the mirror plane because an in-plane spin reverses under mirror reflection. A radial spin texture, that is, parallel spin-momentum locking, has been predicted for chiral elemental semiconductors Te and Se (Hirayama et al., 2015). The Weyl nodes have been identified in Te by ARPES (Nakayama et al., 2017), and the radial spin texture was observed near the Fermi energy by spin-resolved ARPES for chiral Te (Sakano et al., 2020; Gatti et al., 2020), including its reversal for crystals with opposite chirality (Sakano et al., 2020). Gyrotropic effects, i.e., those that reverse with the crystal chirality, have been predicted for Te. A current along the trigonal axis induces a small parallel magnetization, which can be detected by Faraday rotation of transmitted light (Tsirkin et al., 2018).

Te does not exhibit topological semimetal behavior and the radial spin texture is not expected to be maintained in a large range of momentum space. However, theoretical studies have predicted the presence of a truly radial spin texture (Fig. 14L) and an isotropic parallel spin-momentum locking in chiral topological semimetals with single- and multifold band crossings (Chang et al., 2018; Lin et al., 2022). Spin-resolved ARPES investigations have been conducted on PtGa revealing parallel spin-momentum locking for the multifold fermions at Γ and R. This was possible through the spin texture of its topological Fermi arc surface states, which points orthogonal to the Fermi surface contour close to the projection of the bulk multifold fermion (Krieger et al., 2022). This is seen in Fig. 14M,N. Additionally, it has been demonstrated that the direction of spin polarization reverses with the chirality of the crystal (Krieger et al., 2022).

Correlated topological insulators

The topological materials discussed so far are classified based on their single-particle band structure and do not rely on electron correlation. Nonetheless, various research directions explore the connection between topology and strong correlation. One notable limitation of TIs identified thus far is the relatively small size of their inverted bulk band gaps, which restricts their practical use in semiconductor electronics. However, the Coulomb interaction can generate or augment band gaps to much greater magnitudes. In that case their gaps are centered about the Fermi level and do not require a certain stoichiometry such as in $(\text{Bi,Sb})_2(\text{Te,Se})_3$ compounds to become bulk insulating (Dzero and Galitski, 2013).

Generally the electron correlation is stronger among d and f electrons than for s and p electrons. In $5d$ transition metal oxides, both the spin-orbit interaction and the electron correlation are strong and of the same order of magnitude. According to a tight-binding model, Na_2IrO_3 has been predicted to be a quantum spin-Hall insulator, which is a 2D TI (Shitade et al., 2009). It is important to note that there are strongly correlated topological phases of matter that have no analog in band theory and hence do not lend themselves to an investigation of their nontrivial topology by ARPES. This applies to the topological Mott insulator (Raghu et al., 2008; Pesin and Balents, 2010) and extends to frustrated quantum magnetism (Balents, 2010; Reuther et al., 2012).

A prediction directly related to the band structure, and hence relevant for ARPES, applies to SmB_6 , which has been predicted to be a topological Kondo insulator (Dzero et al., 2010; Alexandrov et al., 2013; Takimoto, 2011; Lu et al., 2013). The band gap in a Kondo insulator is caused by hybridization of itinerant conduction electrons, here d electrons, with localized electrons, here f electrons. Importantly, Dzero et al. realized that due to the odd parity of f states and even parity of d states, the precondition for band inversion is fulfilled (Dzero et al., 2010). Band calculations predicted SmB_6 as strong TI with an odd number of Dirac cones on the (100) cleavage plane (Alexandrov et al., 2013; Takimoto, 2011; Lu et al., 2013).

SmB_6 was the first established mixed valent compound and Kondo insulator and the predictions as TI prompted further experimental efforts (see the review by Allen, 2016). Surface transport experiments confirmed subsequently that at low temperatures only the surface remains metallic (Wolgast et al., 2013; Kim et al., 2013). In ARPES, surface states were found at the $\bar{\Gamma}$ and $\bar{X}$ points (Xu et al., 2013a; Jiang et al., 2013), as well as in quantum interference data (Li et al., 2014). ARPES data were consistent in the observation of a Fermi surface contour at $\bar{X}$ (Xu et al., 2013a; Jiang et al., 2013; Neupane et al., 2013; Frantzeskakis et al., 2013; Denlinger et al., 2013; Min et al., 2014). The dispersion of a Dirac cone was, however, not observed at $\bar{\Gamma}$ or at $\bar{X}$.

Hlawenka et al. (2018) demonstrated by core-level spectra two chemically pure terminations, consistent with earlier work (Denlinger et al., 2013). The boron and Sm terminations are also observed in scanning tunneling microscopy and differences in the assignment of scanning tunneling microscopy topographies in the literature have been explained by an element sensitivity due to the bias voltage (Herrmann et al., 2020). Hlawenka et al. (2018) observed that the $\bar{\Gamma}$ state has a massive dispersion for Sm termination and is sensitive to contamination indicating that it is topologically trivial. For the boron termination, it shows a Rashba splitting, which is incompatible with a topological state. Since one $\bar{\Gamma}$ and two $\bar{X}$ Dirac cones have been predicted at the surface (Alexandrov et al., 2013; Takimoto, 2011; Lu et al., 2013), it is actually unimportant for the topological assignment whether the contour at $\bar{X}$ is trivial.

The closing of the $5d$ - $4f$ hybridization gap with increasing temperature has been observed in ARPES (Denlinger et al., 2013; Min et al., 2014; Hlawenka et al., 2018). It was found that the surface state at $\bar{X}$ is a surface shifted hybridized $5d$ - $4f$ dispersion, which is shifted by 10 meV to higher binding energy for boron termination and by about the same amount to lower binding energy for Sm termination (Hlawenka et al., 2018). These shifts, which are consistently observed by scanning tunneling spectroscopy (Herrmann et al., 2020; Matt et al., 2020), are enough to bridge the bulk band gap and explain the robust surface metallicity despite the trivial character of the surface state at $\bar{X}$.

The results by Hlawenka et al. do not explain why Xu et al. (2014) observe a spin texture expected for a TSS for the $\bar{X}$ contour. A similar spin texture was reported for the nonpolar (111) surface (Ohtsubo et al., 2019). Ohtsubo et al. (2019) noted that the

measurement temperatures of 15–20 K (Xu et al., 2014; Ohtsubo et al., 2019) would conflict with the gap energy scale by Hlawenka et al. if confirmed. A spin polarization has also been reported for YbB₁₂ as indication for a TSS (Hagiwara et al., 2016).

Another open question in SmB₆ concerns the umklapp features seen in ARPES. They are consistent with the (2×1) reconstruction of the Sm-terminated surface but appear also on the boron terminated surface, which shows only a (1×1) topography (Herrmann et al., 2020). In view of the trivial character of the observed $\bar{\Gamma}$ state, some researchers propose that the Fermi surface contour around $\bar{\Gamma}$, assigned so far to umklapp from the $\bar{X}$ contour (Xu et al., 2013a; Jiang et al., 2013; Hlawenka et al., 2018), is instead the missing Dirac cone to render SmB₆ topological (Ohtsubo et al., 2019; Thunström and Held, 2021; Li et al., 2020).

Recently, FeSb₂ has been proposed as another candidate for a topological Kondo insulator (Xu et al., 2020). Here, the Fe is mixed valent and the hybridization gap occurs with its 3d states. The system also shows a conductivity plateau similarly to SmB₆. Other suggested compounds include Fe₂VAL, FeSi, and FeGe₃ (Xu et al., 2020; Tomczak, 2018).

Topological superconductors

ARPES has been playing an important role in the investigation of superconductors, in particular at high energy resolution to access the superconducting gap and determine the superconducting pairing symmetry, the pseudogap above the critical temperature, and other properties.

In a topological superconductor, the superconducting gap plays the role of the bulk gap in the TI, and the topological superconductor can be viewed as a TI with particle-hole symmetry (Roy, 2008; Schnyder et al., 2008; Qi and Zhang, 2011). The simplest scenario in which they can be expected to emerge is that where spin-polarized topological surface or edge states span across the Fermi level of a superconducting material (with the superconducting phase possessed either intrinsically or proximity induced). An overall antisymmetric pairing is then possible between electrons populating the TSS branches at $\pm k$. Alternatively, Rashba surface states in magnetic systems could produce similar results (Elliot, 2015; Sato and Ando, 2017). Indeed, time-reversal breaking topological superconductors could provide a platform for topological quantum computing making use of their non-Abelian statistics (Nayak et al., 2008). Proximity between a magnetic TI and an s-wave superconductor has, for example, been suggested for a topological quantum bit (Lian et al., 2018).

Intrinsic superconductors with E_F -pinned topological states at the Fermi level seem to be relatively sparse in nature. Of those that do exist, it is unlikely that an intrinsic superconducting phase can be present without (semi-)metallic ground states, thus precluding the use of genuine TIs for this purpose. Despite this, there are several candidate topological superconductors currently under investigation by ARPES. For the Fe-based superconductor Fe(Te,Se), a bulk band inversion involving strong spin-orbit interaction was predicted (Wang et al., 2015; Xu et al., 2016). This band inversion should lead to Dirac cone TSSs at $\bar{\Gamma}$ of FeTe_{0.55}Se_{0.45} (100). By high-resolution laser ARPES, this surface state was recently reported (Zhang et al., 2018, 2019a). By superconducting proximity to the bulk, the Dirac cone is expected to open a superconducting gap. An isotropic superconducting gap was measured in the upper Dirac cone at $T = 2.4$ K (Zhang et al., 2018). It was recently argued, however, that FeTe_{0.55}Se_{0.45} is a superconducting 3D Dirac semimetal hosting type-I and type-II Dirac points and that its electronic structure remains topologically trivial (Borisenko et al., 2020). Further increase in Te content would possibly create a band inversion, however, only with sub-meV sized gap (Borisenko et al., 2020). Similarly, the superconducting Dirac semimetal 1T-PdTe₂ has TSSs that cross the Fermi level, but scanning tunneling spectroscopy/microscopy and muon spin relaxation experiments have found only conventional superconducting pairing to date (Clark et al., 2018; Leng et al., 2019).

Ultrafast experiments

Time-resolved pump-probe ARPES experiments of topological matter allow for the study of unoccupied states, in particular TSSs, and the dynamics of excited charge carriers including their relaxation mechanisms (Sobota et al., 2012; Wang et al., 2012a), the spin texture of unoccupied states (Sánchez-Barriga et al., 2016; Jozwiak et al., 2016; Clark et al., 2021), and novel light-induced emergent phenomena (Wang et al., 2013a).

Upon ultrafast excitation of a TI with infrared (~ 1.5 eV) laser pulses of 50 fs, electrons from the Dirac cone and the bulk valence band are excited. Within a few 100 fs they occupy states above the Fermi level of the Dirac cone as well as the bulk conduction band, as seen with probe pulses of ~ 6 eV (Sobota et al., 2012; Wang et al., 2012a). For these experiments, conventional *n*-type Bi₂Se₃ has been used (Wang et al., 2012a) as well as special *p*-type Bi₂Se₃ samples (Sobota et al., 2012), see Fig. 15A. Immediately after the excitation, a thermalized electron distribution is reached in the TSS and in the bulk conduction band (Wang et al., 2012a). The thermalization, which can be probed at the Fermi-Dirac cutoff of the excited electron distribution, occurs due to electron-electron scattering. Since the maximum population of the TSS of *p*-type Bi₂Se₃ was reached at ~ 700 fs, higher-lying states are likely involved in the population (Sobota et al., 2012). The decay is noticeable after ~ 2 ps. This timescale is identified with energy transfer from the electrons to the lattice and thus characteristic for electron-phonon scattering in the bulk of Bi₂Se₃. The dynamics persist, however, at a timescale > 10 ps. The reason is a second, slower component below the bulk conduction band edge. This slow component decays with the same timescale as the bulk conduction band population because the TSS is continuously filled by the slowly decaying bulk conduction band occupation (Sobota et al., 2012).

Fig. 15 Ultrafast pump-probe spectroscopy from Bi₂Se₃, Sb₂Te₃, and Bi₂Te₃. (A) Ultrafast populated unoccupied bulk conduction band states and the upper Dirac cone of *p*-type Bi₂Se₃ decay with a time constant that increases toward the Dirac point due to a bottleneck effect. (B) Bloch-Floquet states in Bi₂Se₃ due to coherent interaction of photons and electrons. Intensity of sidebands is maximum where pump and probe pulse maximally overlap ($t = 0$ ps). (C,E) Circularly polarized pump pulses create in Sb₂Te₃ a transient out-of-plane spin polarization in the Dirac cone determined by the light helicity, here shown for $t = 500$ fs. (C,D) Circular dichroism reveals that more electrons with momentum along $+k$ can be excited than along $-k$. (F) This asymmetry in the Dirac cone has for Bi₂Se₃ a threefold symmetry excluding a net effect on the (spin-polarized) photocurrent. (G–I) Acceleration of electrons in the TSS of Bi₂Te₃ by a THz pulse. The effect reverses with the sign of the electric field, shown in panel (H). (I) *Blue (red)* denotes the branch of the Dirac cone for negative (positive) momenta. Panel (A) taken from Sobota JA, Yang S, Analytis JG, Chen YL, Fisher IR, Kirchmann PS, and Shen Z-X (2012) *Physical Review Letters* 108: 117403; panel (B) from Mahmood F, Chan C-K, Alpichshev Z, Gardner D, Lee Y, Lee PA, and Gedik N (2016) *Nature Physics* 12: 306–310; panels (C–E) from Sánchez-Barriga J, Vergniory MG, Evtushinsky D, Aguilera I, Varykhalov A, Blügel S, and Rader O (2016b) *Physical Review B* 94: 161401(R); panel (F) from Ketterl AS, Otto S, Bastian M, Andres B, Gahl C, Minár J, Ebert H, Braun J, Tereshchenko OE, Kokh KA, Fauster T, and Weinelt M (2018) *Physical Review B* 98: 155406; panels (G–I) from Reimann J, Schlauderer S, Schmid CP, Langer F, Baierl S, Kokh KA, Tereshchenko OE, Kimura A, Lange C, Güdde J, Höfer U, and Huber R (2018) *Nature* 562: 396.

The combination of time- and spin-resolved ARPES allows to study the spin texture of unoccupied TSSs and the bulk conduction band. Again, *p*-type samples such as Sb₂Te₃ leading to an unoccupied upper and largely occupied lower Dirac cone (Zhu et al., 2015) are advantageous for studying the decay processes (Sánchez-Barriga et al., 2016). The spin texture forbids a vertical transition within the Dirac cone. For horizontal transitions involving phonons, the limitation is the maximum phonon energy, which is about 25 meV for Sb₂Te₃, similarly to Bi₂Se₃ (Hatch et al., 2011). The deceleration of the recombination due to lack of available states is sometimes referred to as electron bottleneck effect. It can be seen directly in the data as enhanced transient photoemission intensity above the Dirac point. Measured relaxation rates were 5–10 ps for Bi₂Se₃ (Sobota et al., 2012; Wang et al., 2012a), 50 ps for *p*-type Bi₂Te₃ (Hajlaoui et al., 2014), and 1.5 ps for Sb₂Te₃ (Sánchez-Barriga et al., 2016). Experiments with spin resolution allow to conclude whether spin manipulation with circularly polarized light, confirmed for continuous 6 eV ultraviolet light in Bi₂Se₃ (Jozwiak et al., 2013), will extend to the infrared range. Spin- and time-resolved ARPES of Sb₂Te₃ shows that a circularly polarized

pump pulse turns the spins of the Dirac cone from in plane to out of plane in the transient state (Sánchez-Barriga et al., 2016), see Fig. 15C and E. Similarly to the direct photoemission experiment at 6 eV (Jozwiak et al., 2013; Sánchez-Barriga et al., 2014b) the spin orientation is determined by the light helicity (C+ and C-). This means that the spin manipulation does not only affect the final state of photoemitted electrons but also rotates the spin of electrons inside of the sample, an effect that could be employed for opto-spintronics (Sánchez-Barriga et al., 2016). This has been confirmed also for excitation into higher-lying surface states and resonances (Soifer et al., 2019). It was also possible to measure the decay of the spin polarization of the excited carriers which occurs twice as fast as the spin-averaged intensity, on a time scale of 0.4 ps as compared to 1 ps for the electron population (Sánchez-Barriga et al., 2016). The constant indirect filling of the bulk conduction band (Sobota et al., 2012) probably leads to a depolarization since it supplies unpolarized electrons from the bulk valence band (Sánchez-Barriga et al., 2016).

The above is also an example for the importance of the coupling of surface and bulk states. The coupling of surface resonances to the bulk was found to be comparatively weak for Sb_2Te_3 (Seibel et al., 2015) and Bi_2Se_3 (Cacho et al., 2015). For the *n*-doped systems Bi_2Se_3 and Bi_2Te_3 , infrared light can excite electrons directly into higher lying surface resonances (Cacho et al., 2015), which plays a crucial role in the spin dynamics (Cacho et al., 2015; Sánchez-Barriga et al., 2017b).

When the stoichiometry is tuned to the bulk insulating state in $(\text{Bi,Sb})_2\text{Te}_3$, the decay time increases dramatically from a few ps to several 100 ps (Sánchez-Barriga et al., 2017a; Sumida et al., 2017). A persistent photovoltage is observed and interpreted as caused by band bending (Sánchez-Barriga et al., 2017a). Thermalized electrons cannot diffuse from the surface state into the bulk while bulk holes diffuse to the surface. This special situation due to the intrinsically metallic surface has been suggested for use in photovoltaics (Sánchez-Barriga et al., 2017a). However, when Sb_2Te_3 is magnetically doped by V, the decay time decreases again strongly due to additional scattering paths, for example, at 0.33 eV above the Fermi level from ~ 3 ps to ~ 100 fs (Sumida et al., 2019).

In order to make use of TIs in spintronics, it is necessary to generate spin currents or spin-polarized currents, for example, for spin-transfer torques as generated in TI/ferromagnet interfaces (Mellnik et al., 2014). It has been reported that spin-polarized currents can be triggered and controlled by circularly polarized infrared radiation of 1.5 eV (McIver et al., 2012) but this result is awaiting confirmation by spectroscopic methods. The intensity enhancement in ARPES upon ultrafast excitation (Sobota et al., 2012; Wang et al., 2012a) becomes visibly asymmetric in electron momentum $k_{\parallel}$ for Sb_2Te_3 when the infrared light pulse is circularly polarized (Sánchez-Barriga et al., 2016), see Fig. 15C and D. Because of the locking of spin and linear momentum in the Dirac cone, this finding was interpreted as confirmation that an ultrafast spin-polarized current is excited by the circularly polarized infrared light (Sánchez-Barriga et al., 2016). With smaller excitation energies of 0.25 to 0.37 eV, the asymmetry in momentum is also strong but does not reverse by switching the light helicity (Kuroda et al., 2016). On the other hand, it has been pointed out for Bi_2Se_3 that the helicity-dependent asymmetry, that is, the circular dichroism, has at the Fermi energy a threefold asymmetry in the (k_x, k_y) momentum plane and, therefore, cannot lead to an overall spin-polarized current (Ketterl et al., 2018), see Fig. 15F.

Time-resolved ARPES has also been used to investigate carrier-wave-driven currents in the TSS (Reimann et al., 2018). With subcycle time resolution, the acceleration by the carrier wave of a THz pulse of electrons in the TSS of Bi_2Te_3 is probed. The branches appear shifted in energy and momentum with respect to each other marking the shift of the Fermi circle in momentum space, see Fig. 15G–I. The effect reverses when the electric field as marked in Fig. 15H changes sign. It is concluded that large ballistic mean free paths result from spin-momentum locking (Reimann et al., 2018).

Strong coupling of electronic states with photons can lead to Floquet–Bloch states, which are periodic in momentum and energy (Faisal and Kaminski, 1997). This has been demonstrated for the TSS of Bi_2Se_3 using intense ultrashort mid-infrared pulses the energy of which is below the bulk band gap (Wang et al., 2013a; Mahmood et al., 2016). It leads to the appearance of Dirac cone replicas above and below the original Dirac cone spaced by the driving photon energy, see Fig. 15B. Important for the confirmation as Floquet–Bloch states was the observation of hybridization gaps between these side bands (Wang et al., 2013a). In addition, a gap at the Dirac point was created using circularly polarized light and assigned to time-reversal symmetry breaking and the creation of a photoinduced quantum anomalous Hall phase (Wang et al., 2013a).

Conclusion

We end by highlighting a few aspects that we consider important for the future development of ARPES in topological materials.

The theoretical prediction of topological materials based on their band structure has recently been performed systematically (Bradlyn et al., 2017; Po et al., 2017; Kruthoff et al., 2017). Under the theory of topological quantum chemistry, band structures and symmetry groups are systematically analyzed by graph theory and group theory, respectively, and topologically nontrivial band structures can be systematically discovered. The nontrivial topology must be inherent in the band structure—as opposed to topological phases such as spin liquids—and electron correlation must be weak. ARPES will continue to directly verify these predictions and will contribute to explore the effects of electron correlation.

Micro- and nano-ARPES (see the review by Hofmann, 2021) will lift the constraints to grow large single crystals. Small crystalline domains or small single crystals can be studied but the surface preparation by cleaving will become more challenging and novel approaches will be required. Micro/nano-ARPES will also enable to distinguish differently stacked local regions in stacked 2D materials such as TMDs and MXenes (Gogotsi and Anasori, 2019).

In the general framework of future electronics, one can say that the transistor-based electronics, which is currently in use, faces limitations when it comes to further downsizing. Additionally, its operation relies on relatively uncomplicated materials.

In contrast, topological and other quantum materials possess distinct sensitivity to external influences. In the case of topological protection, this sensitivity can be extremely low. On the other hand, the sensitivity can be significantly high. In-operando ARPES can uncover such substantial state changes in response to electric current, bias voltage, electric field, temperature, and strain. In this way, topological phase transitions can be driven, and the effects may be leveraged in innovative devices. The phase space for the choice of the ideal material is enormously expanded in this way, and a material can be picked and further properties induced separately. This includes proximity effects as discussed above in the context of topological superconductivity. Dissipationless quantized edge states and functionalities required for topological quantum computations could thus be investigated in device-like structures.

Hence, another use of the high spacial resolution of micro/nano-ARPES will relate to in-operando use of ARPES (Hofmann, 2021). It has been shown for graphene and bilayer graphene stacked with h-BN that the effect of gating can be resolved (Joucken et al., 2019; Nguyen et al., 2019a; Curcio et al., 2020). It has also been achieved for the flat band of twisted bilayer graphene (Jones et al., 2020) and for WSe_2 (Nguyen et al., 2019a).

It would be a strong advantage to determine the nontrivial topology directly in ARPES. For topological matter simulated by ultracold atomic gases, the quantization of circular dichroism in photoabsorption was demonstrated as distinct differentiation between topologically trivial and nontrivial phases (Asteria et al., 2019). Deducing the Berry phase from the CDAD has been proposed and calculated for graphene (Liu et al., 2011; Gierz et al., 2012; Schüler et al., 2020), monolayer WTe_2 (Muechler et al., 2016), and bulk 2H-WSe_2 (Cho et al., 2018). It will be interesting to see how final-state effects can be treated and whether it will be possible to investigate arbitrary 3D materials.

Reflection and Transmission

Metals are characterized by large electrical conductivity and shiny surfaces, that is, intense reflectivity. Because both properties are responses to electromagnetic fields, there is a close connection.

For a transparent discussion, Maxwell's equations which govern optics are presented, with polarization, magnetization, and current shown explicitly:

$$\nabla \times \mathbf{B} = \mu_0 \epsilon_0 \frac{\partial \mathbf{E}}{\partial t} + \mu_0 (\mathbf{j} + \nabla \times \mathbf{M}) \quad [1]$$

$$\nabla \cdot \mathbf{E} = \frac{1}{\epsilon_0} (\rho - \nabla \cdot \mathbf{P}) \quad [2]$$

$$\nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t} \quad [3]$$

$$\nabla \cdot \mathbf{B} = 0 \quad [4]$$

Here, it is clearly seen that $-\nabla \cdot \mathbf{P}$ acts as a source of the electric field like any charge and $\partial \mathbf{P} / \partial t$ (and $\nabla \times \mathbf{M}$) creates $\mathbf{B}$ like any current. This is easily understood from the definition of the polarization $\mathbf{P}$ as the amount of charge penetrating a plane normal to $\mathbf{P}$ when the polarization is created. It is conventional to distinguish between true charges ρ and apparent charges $-\nabla \cdot \mathbf{P}$, true currents $\mathbf{j}$ and apparent currents $(\partial \mathbf{P} / \partial t + \nabla \times \mathbf{M})$. $\mathbf{P}$ is then considered due to the shift of bound charges (such as in an oscillator-model). But it is obvious that at very high frequencies with short shifts of all charges, the distinction between free and bound charges will not be possible any more. It is impracticable in metal optics. It is only a theoretical concept. One effectively deals with a total response to the electromagnetic fields and therefore with an effective response function: a complex dielectric function ϵ , a complex conductivity σ , or a complex polarizability $\chi = \epsilon - 1$.

Next, linear isotropic responses are assumed:

$$\mathbf{j} = \sigma \mathbf{E}, \quad \mathbf{P} = \chi_p \epsilon_0 \mathbf{E}, \quad \mathbf{M} = \chi_m \mathbf{H} \quad [5]$$

$$\mathbf{D} = \epsilon_0 \mathbf{E} + \mathbf{P} = \epsilon_0 (1 + \chi_p) \mathbf{E} = \epsilon_0 \epsilon_p \mathbf{E} \quad [6]$$

$$\begin{aligned} \mathbf{B} &= \mu_0 (\mathbf{H} + \mathbf{M}) = \mu_0 (1 + \chi_m) \mathbf{H} \\ &= \mu_0 \mu \mathbf{H}, \quad \epsilon_0 \cdot \mu_0 = \frac{1}{c^2} \end{aligned} \quad [7]$$

The relation between polarizability and conductivity can be derived by reordering of eqns [1] and [2] to the more conventional form

$$\nabla \times \mathbf{H} = \frac{\partial \mathbf{D}}{\partial t} + \mathbf{j} = \frac{\partial}{\partial t} \mathbf{D}_{\text{eff}} \quad [8]$$

$$\nabla \cdot \mathbf{D} = \rho \quad [9]$$

$\mathbf{D}_{\text{eff}}$ is easily defined for each time Fourier component. A periodicity $e^{-i\omega t}$ for all optical fields is introduced (the minus sign is chosen arbitrarily, but it determines many signs from now on) and one gets from [8] and [3]

$$\nabla \frac{1}{\mu_0 \mu} \mathbf{B} = -i\omega (\epsilon_0 \epsilon_p - \frac{\sigma}{i\omega}) \mathbf{E} = -i\omega \mathbf{D}_{\text{eff}} \quad [10]$$

$$\nabla \times E = +i\omega B \quad [11]$$

$$\nabla \times (\nabla \times E) = \nabla(\nabla \cdot E) - \Delta E = \frac{\omega^2}{c^2} \mu(\epsilon_p - \frac{\sigma}{i\omega\epsilon_0})E \quad [12]$$

As explained at the beginning, the polarizability and the conductivity are found to be on the same footing in the wave equation [12] and therefore, the effective complex dielectric function is defined as

$$\epsilon = 1 + \chi_p - \frac{\sigma}{i\omega\epsilon_0}, \quad D_{\text{eff}} = \epsilon_0 \epsilon E \quad [13]$$

In standard metal optics, it is argued that in conducting metals any charge ρ is quickly dissipated or screened and eqn [2] yields effectively $\nabla \cdot E = 0$. An estimate of the decay time of a charge can be got by putting eqn [9] into the continuity equation

$$\dot{\rho} = -\nabla \cdot j = -\sigma \nabla \cdot E = -\frac{\sigma}{\epsilon_0 \epsilon_p} \rho \quad [14]$$

$$\rho = \rho_0 \cdot e^{-t/\tau}, \quad \text{with} \quad \tau = \frac{\epsilon_p \epsilon_0}{\sigma} \quad [15]$$

For silver with $\sigma = (0.016 \times 10^{-4} \Omega \text{cm})^{-1}$ and, $\epsilon_p \approx 1$, the decay time $\tau \approx 10^{-19}$ s and, therefore, charges decay faster than most optical fields vary. This estimate with the static conductivity is too optimistic. It is seen later that around $\omega \approx 10^{16} \text{s}^{-1}$ ($\hbar\omega > 3.5 \text{ eV}$) charge density waves, plasma waves with $\nabla \cdot E \neq 0$, play a role in optics. But in the regime of visible optics with $\nabla \cdot E = 0$ and eqn [13], the level of standard optics was attained with transverse waves and the complex index of refraction

$$\tilde{n} = \sqrt{\epsilon \mu} \quad [16]$$

In most metals, $\mu \approx 1$ is a valid approximation. A treatment of the reflection from the surface of a metal with dielectric function ϵ_M facing a transparent medium (ϵ_1) yields the standard Fresnel formulas, which for later use are derived in a handy notation for wave vectors in the xz -plane, surface normal $||z$ into the metal:

$$\text{in medium 1: } E(\mathbf{r}, \omega) = E_0 e^{i(k_x x + qz)} + R e^{i(k_x x - qz)} \quad [17]$$

$$\text{in the metal: } E(\mathbf{r}, \omega) = T e^{i(k_x x + lz)} \quad [18]$$

$$q = \sqrt{\frac{\omega^2}{c^2} \epsilon_1 \mu_1 - k_x^2}, \quad l = \sqrt{\frac{\omega^2}{c^2} \epsilon_M \mu_M - k_x^2} \quad [19]$$

p - and s -polarization are distinguished and so are E parallel or normal to the plane of incidence, here the xz -plane. Because R and T are orthogonal to their respective wave vectors, only the two z -components have to be determined for p -polarization (the two amplitudes for s -polarization). Therefore, the two standard boundary conditions are used:

$$\text{continuity of } E_{\text{tangential}} \text{ or } B_{\text{normal}} \quad [20]$$

$$\text{continuity of } D_{\text{eff,normal}} \text{ or } H_{\text{tangential}} \quad [21]$$

Here, an obvious problem is usually brushed under the carpet – what the continuity of the normal component of D from $\nabla \cdot D = 0$ (eqn [19] with $\rho = 0$) or of D_{eff} from $\nabla \cdot D_{\text{eff}} = 0$ as eqn [8] or [10] tells us. Because this problem is difficult, one takes refuge in the continuity of H_{tg} which actually makes $D_{\text{eff,normal}}$ continuous as a consequence of [8] or [10]. Continuity of H_{tg} requires (from [8]) all fields to be finite, here D , and no singular surface currents. But the discontinuity of E_{normal} , which goes with the continuity of $D_{\text{eff,normal}} = \epsilon_0 \epsilon E_{\text{normal}}$ and a discontinuous ϵ , requires singular surface charges, from eqn [2]. Arguing with bound charges $-\nabla \cdot P$ does not help because $\chi_p = 0, P = 0$ is often a good description of the metal. Also the normal component of $j = \sigma E$ is discontinuous.

For frequencies in the visible approximation, [21] works. Around the eigenfrequency of the electrons, the plasma frequency ω_p , the charges, and the currents get so large that the problem behind boundary condition [21] must be solved. This is done in the section “Plasma waves in metal optics.”

Boundary conditions [20] and [21] yield two linear equations for the reflection and transmission amplitudes. They are related to the reflection and transmission coefficients r and t :

$$\begin{aligned} p\text{-polarization: } \frac{R_z}{E_{0z}} &= \frac{\epsilon_M q - \epsilon_1 l}{\epsilon_M q + \epsilon_1 l} \\ \frac{T_z}{E_{0z}} &= \frac{2q\epsilon_1}{\epsilon_M q + \epsilon_1 l} \end{aligned} \quad [22]$$

$$r = \left| \frac{R_z}{E_{0z}} \right|^2, \quad t = \frac{l\epsilon_M}{q\epsilon_1} \left| \frac{T_z}{E_{0z}} \right|^2 \quad [23]$$

$$\begin{aligned} s\text{-polarization} : \quad \frac{R}{E_0} &= \frac{q\mu_M - l\mu_1}{q\mu_M + l\mu_1}, \\ \frac{T}{E_0} &= \frac{2q\mu_M}{q\mu_M + l\mu_1} \end{aligned} \quad [24]$$

$$r = \left| \frac{R}{E_0} \right|^2, \quad t = \frac{l\mu_1}{q\mu_M} \left| \frac{T}{E_0} \right|^2 \quad [25]$$

In the infrared, the term $\sigma/(\omega\epsilon_0)$ in eqn [13] is much larger than 1. If $\mu_M \approx \mu_1$ and $\epsilon_1 = 1$, the reflection coefficient for normal incidence ($k_x \rightarrow 0$) can be expanded:

$$r = \left| \frac{\tilde{n}_M - 1}{\tilde{n}_M + 1} \right|^2 \approx 1 - 2\sqrt{2\frac{\omega\epsilon_0}{\sigma}} \quad [26]$$

This is called the Hagen–Rubens relation for the decrease of the metallic reflectivity due to the finite conductivity. It is a good approximation (with the static conductivity) for most metals in the infrared for $\lambda > 10\mu\text{m}$.

For further discussion of the consequences of eqns [22]–[25], a model for the metallic response is considered, the Drude model, which approximates well the typical properties of metals. It considers only the conducting electrons. It could easily be supplemented by a Debye oscillator model for underlying bound electrons, the polarizability χ_p which could then simply be added as in eqn [13]. The Drude model is the equation of motion of the collection of electrons driven by the electric field and suffering a friction:

$$m\ddot{\mathbf{r}} = -e_0\mathbf{E} - m\gamma\dot{\mathbf{r}}, \quad \mathbf{j} = -e_0n_0\dot{\mathbf{r}} \quad [27]$$

$$\frac{\partial}{\partial t}\mathbf{j} = \frac{n_0e_0^2}{m}\mathbf{E} - \gamma\mathbf{j} = \omega_p^2\epsilon_0\mathbf{E} - \gamma\mathbf{j} \quad [28]$$

The plasma frequency is introduced here via the mean conduction electron density n_0 :

$$\omega_p = \left(\frac{n_0e_0^2}{m\epsilon_0} \right)^{1/2} \quad [29]$$

and the friction constant $\gamma = 1/\tau$ related to the collision time τ . The Drude model (eqn [28]) leads to the static conductivity

$$\sigma_{\text{stat}} = \frac{n_0e^2}{m\gamma} = \frac{n_0e^2}{m}\tau$$

but more relevantly here to the optical conductivity:

$$\sigma(\omega) = \frac{i\omega_p^2\epsilon_0}{\omega + i\gamma} \quad [30]$$

and from eqn [13] ($\chi_p = 0$) to the typical metal dielectric function:

$$\epsilon = 1 - \frac{\omega_p^2}{\omega^2 + i\omega\gamma} \quad [31]$$

From the static conductivity, one can derive an estimate for τ or $\gamma \approx 10^{10}\text{s}^{-1}$, and find that at least for the visible frequencies, a good approximation is

$$\epsilon(\omega) \approx 1 - \frac{\omega_p^2}{\omega^2} \quad [32]$$

ϵ is negative for small frequencies ω , $\epsilon = 0$ at $\omega = \omega_p$, and approaches 1 for values smaller than 1 for large ω .

The negative values of ϵ are responsible for the high reflectivity. In eqn [19] l is purely imaginary and $r = 1$ in [23] and [25] because the numerator and denominator are a conjugate complex. The imaginary l says that the electromagnetic waves do not travel inside the metal, but the fields decay exponentially with the penetration depth

$$d = \frac{1}{|l|} = \left| \left(\frac{\omega^2}{c^2} \mu \epsilon \right)^{1/2} \right|^{-1} = \frac{\lambda_0}{2\pi|\epsilon|^{1/2}} \quad [33]$$

much smaller than the vacuum wavelength λ_0 . At very low frequencies, ϵ is determined by γ (eqn [31]), varies little, and d decreases with growing frequency (“skin effect”). There is a turnover (“anomalous skin effect”) when $|\epsilon|$ decreases and approaches zero at ω_p (eqn [32]). At ω_p , l becomes real, the waves are transmitted inside the metal, and the metal becomes transparent.

This threshold of transparency, ω_p , is characterized by the density of conduction electrons in simple metals (eqn [29]). This transparency is not seen because the plasma frequencies lie in the near to far ultraviolet (for tables of plasma frequencies, see “Further reading” section).

Formally, metal optics is normally developed completely parallel to the optics of transparent media. Only the dielectric function is different. It is purely imaginary, $\sim\sigma$, in the infrared (eqn [13]), mainly real and negative in the visible (eqns [31] and [32]), has a zero at ω_p in the near ultraviolet beyond which the metal is transparent with an index of refraction smaller than 1 (eqn [32]). At frequencies below ω_p , electromagnetic fields decay exponentially inside the metal and the optical energy is reflected.

Due to the fact that ε always has some real and some imaginary part, the statements just made are approximate. Around ω_p , for instance, ε (eqn [31]) does not go exactly through zero, and there is a smooth transition from the wave vector $k = (\omega/c)\sqrt{\mu\varepsilon}$ being dominated by the imaginary part to the propagating frequencies with mainly real k , from the anomalous skin effect to transparency.

The approximation [27]–[32], essentially for nearly free electrons, does not work well for d -band transition metals or for the lanthanides. For these metals, a model must at least include a polarizable background leading to an additional χ_p as in eqn [13]. The screening by this background can shift the frequency for $\varepsilon(\omega)\approx 0$ drastically, for example, for silver, from $\hbar\omega_p = 9$ eV according to eqn [29] to the measured $\hbar\omega_p = 3.8$ eV.

In most frequency regions of interest in optics, one cannot determine the index of refraction $\tilde{n} = n(1+i\kappa) = \sqrt{\mu\varepsilon}$ from the angle of refraction and from light attenuation (absorption). One has to use the information in reflection. The difference in reflectivity of s - and p -polarized light is exploited in ellipsometry. When linearly polarized light with an (equal) s - and p -component is reflected from a metal surface, there generally appears a difference in phase and amplitude of the reflected components leading to elliptical polarization in the reflected beam. Measurements of the ellipse, the rotation angle of the main axis, and the difference of the two main axes, allow the determination of the real and imaginary part of $\tilde{n}$ or ε , because the reflection amplitudes eqns [22] and [24] contain the relations. The realm of variation of the phase on reflection can be easily estimated from the reflection amplitudes [22] and [24]. The transversality means $R_x = (q/k_x)R_z$ and $E_{0x} = -(q/k_x)E_{0z}$, $R_x/E_{0x} = -R_z/E_{0z}$. Then for normal incidence ($k_x \rightarrow 0$), s - and p -reflection amplitudes are the same:

$$\frac{R_x}{E_{0x}} = \frac{\sqrt{\varepsilon_1\mu_M} - \sqrt{\varepsilon_M\mu_1}}{\sqrt{\varepsilon_1\mu_M} + \sqrt{\varepsilon_M\mu_1}} \approx \frac{\tilde{n}_1 - \tilde{n}_M}{\tilde{n}_1 + \tilde{n}_M} \quad [34]$$

(for $\mu_1 \approx \mu_M \approx 1$ and $\tilde{n} = \sqrt{\varepsilon}$)

If the angle of incidence grows up to glancing incidence ($q \rightarrow 0$), the limits are: for p -polarization $R_x/E_{0x} \rightarrow 1$, for s -polarization $R/E_0 \rightarrow -1$, that is, a phase difference of π . Therefore, one can expect an angle θ , called “the principle angle of incidence,” at which the phase difference is $\delta = \pi/2$, that is, circularly polarized light is reflected as linearly polarized. This angle for metals is reminiscent of the Brewster angle for nonmetallic reflectors, which is seen when the numerator in the p -reflection amplitude eqn [22] is zero. Strongly negative ε_M prohibits such a zero. A Brewster angle is also found for metals in the transparent region beyond ω_p , when the imaginary part of ε is small.

The measured effective dielectric functions ε or indices of refraction $\tilde{n}$ of many metals for different frequency regions can be found in several tables (see the “Further reading” section).

Because metal optics is often studied with very thin metal layers, it may be mentioned again that the distinction between nonpropagating and propagating waves is not sharp because l in eqn [19] always has a real and an imaginary part due to the complex ε . Formally, the fields inside the metal and the transmitted field are calculated as in standard optics: general solution on top, general solution inside, general solution below, and the four amplitudes (reflected, down and up inside, transmitted) determined from the four boundary conditions, [20] and [21] at each surface. This yields the exact fields everywhere. There is no use in summing an infinite series of scatterings from the top and bottom of the layer (and approximating this summation by one or two reflections).

The metal optics described so far is essentially a summary of the relevant chapters in the famous book of Born and Wolf, where extensions and details can be found (see the “Further reading” section).

Surface Plasmon Polaritons

In the region where $\varepsilon < 0$, the reflection amplitude eqn [22] has no zero in the numerator, therefore there is no Brewster angle; but the denominator can be zero (eqn [35]). For those values of ω and k_x , there can be reflected and transmitted amplitudes when the incident field vanishes: one finds eigensolutions of the system, which are called surface polaritons or surface plasmon polaritons (SPP) or surface plasmons. Their dispersion relation $\omega_s(k_{\text{tangential}})$ or $k_{\text{tg}}(\omega_s)$ is found from eqns [22] and [19]:

$$\varepsilon_M(\omega_s) \sqrt{\frac{\omega_s^2}{c^2} \varepsilon_1 \mu_1 - k_{\text{tg}}^2} + \varepsilon_1 \sqrt{\frac{\omega_s^2}{c^2} \varepsilon_M(\omega_s) \mu_M - k_{\text{tg}}^2} = 0 \quad [35]$$

$$k_{\text{tg}} = \frac{\omega_s}{c} \sqrt{\frac{\varepsilon_M(\omega_s) \varepsilon_1}{\varepsilon_M(\omega_s) + \varepsilon_1}} (\mu_M = \mu_1 = 1) \quad [36]$$

The SPP dispersion relations [35] and [36] are best discussed with ε approximated by eqn [32]. For small frequencies ω_s , an expansion with respect to ω_s/ω_p yields

$$k_{\text{tg}} = \frac{\omega_s}{c} \sqrt{\varepsilon_1} \left(1 + \frac{1}{2} \varepsilon_1 \frac{\omega_s^2}{\omega_p^2}\right) \quad [37]$$

while $k_{\text{tg}} \rightarrow \infty$ when the denominator in [36] goes to zero at

$$\omega_s \rightarrow \frac{\omega_p}{\sqrt{1+\varepsilon_1}} \text{ or } \omega_s \rightarrow \frac{\omega_p}{\sqrt{2}} \text{ (for } \varepsilon_1 = 1) \quad [38]$$

Solutions of eqn [36] for small k_{tg} and $\omega > \omega_p$ are not eigenmodes but indicate the Brewster angle. The dispersion relation for the SPP is shown schematically in Figure 1.

One essential point is that $k_{\text{tg}} > (\omega/c)\sqrt{\varepsilon_1}$ (see eqn [37]), that is, the wavelength of the SPP is shorter than the wavelength of light at the same frequency in the medium 1 above the metal surface, the eigenmode lies "to the right of the light line $k = (\omega/c)\sqrt{\varepsilon_1}$." Therefore, according to eqn [19], the z -components q and l of the wave vector of the surface wave are imaginary; the electromagnetic fields decay exponentially toward both sides of the surface. The excitation energy in the eigenmode is bound to the surface and does not radiate away. On the other hand, this eigenmode cannot directly couple to, or be excited by the light incident on the surface, because even for grazing incidence, k_{tg} of the light is too small; the periodicity parallel to the surface does not match the one of the SPP. At very large k_{tg} , the eigenfrequency rises above the limit of eqn [38] in Figure 1. This is a real plasma effect and is treated in the following section.

These eigenmodes were first derived by Zenneck and Sommerfeld, who explained the transmission of radio waves along the ocean surface. At metal surfaces, they were first seen as energy losses of electrons scattered from metal layers. In optics, it is possible to couple to the SPP if the incident light comes through a prism which shortens λ or increases k . In Figure 1, the SPP dispersion is shown for a metal surface towards vacuum or air ($\varepsilon_1 = 1$). Also indicated is the "light line" $(\omega/c)\sqrt{\varepsilon_{\text{prism}}} = k$. For angles of incidence φ with

$$k_x = \sin \varphi \frac{\omega}{c} \sqrt{\varepsilon_{\text{prism}}} > \frac{\omega}{c} \quad [39]$$

the light is totally reflected from the prism–air interface because l (eqn [19]) in air becomes imaginary. But when this prism surface is brought in close proximity to the metal surface, at the angle where k_x from [39] fulfills the dispersion relation of the SPP [36], the eigenmode is excited, it develops large fields, soaks up energy, and attenuates the total reflection of the prism. This attenuated total reflection (ATR) method has been widely used to study the SPPs as well as the properties of layers adsorbed on metal surfaces, because adsorbed layers shift the dispersion according to $\varepsilon_1 \neq 1$ in eqn [36]. The large fields near the metal surface, when the SPP is excited, have been used to excite molecules especially brought near the surface. On the other hand, a microscope has been built on the ATR principle in order to see structures in adsorbed layers, which appear in self-organized surface reactions. The SPP can be excited by one prism, then travel along the metal surface and be coupled out by a second prism, and the metal surface between the prisms can be manipulated.

The narrow coupling condition that k_x of the exciting light must fulfill the SPP dispersion eqn [36] is true when the metal surface is translationally invariant. Surfaces with some roughness or any local obstacles can scatter light especially strong near $\omega = \omega_p/\sqrt{1+\varepsilon_1}$, where the density of eigenmodes is very high. If a periodic structure is established on the metal surface, for example, a grid of grooves, the related reciprocal lattice vectors can be added or subtracted to k_{tg} in order to overcome the restrictions for SPP excitation. Then refolding of $\omega_s(k_{\text{tg}})$ and gaps due to Bragg diffraction apply as in electron band structures, and there appear possibilities for coupling the SPPs to incident light. Also any irregularities, roughness, adsorbed molecules or metal clusters, which break the translational invariance of the surface, make excitation of surface modes possible. These often lead to extremely large fields around the imperfections. An example is surface-enhanced Raman scattering (SERS) from adsorbed molecules on silver.

Surface waves also play a role when light is transmitted through apertures smaller than the wavelength as in near-field microscopy. Recently, it was shown that light is transmitted through an array of narrow holes in a thick metal layer at a surprisingly

Figure 1 The surface plasmon dispersion. At "+" the wave in a prism can couple to the SPP in an ATR configuration.

large rate. Also, this phenomenon is explained via excitation of SPPs. The same mechanism leads to strong absorption at special frequencies in a system of grooves on a metal surface.

Generally, the excitation of SPPs leads to strong absorption of energy in the metal, to an attenuation of reflection, because the large fields of the eigenmode cause large currents and large losses in the metal. Occasionally, one finds high-energy transport at the excitation condition leading to strong scattering or even high transmission through narrow holes.

When the metal layer is thin enough, the two surfaces excite each other. Then the surface modes on both sides couple symmetrically or antisymmetrically, and the dispersion relations are changed.

Plasma Waves in Metal Optics

In 1953, Bohm and Pines discovered that the electrons in metals can sustain charge density waves with longitudinal electric fields. In an electron gas model of a metal, they found the dispersion relation for plasma waves:

$$\omega^2 = \omega_p^2 + \beta k^2 \quad [40]$$

The Drude model (eqn [28]) leads to plasma oscillations. Taking the divergence of eqn [28] and using the continuity equation and eqn [9] yields

$$\rho = -\omega_p^2 \rho - \gamma \dot{\rho} \quad [41]$$

that is, damped oscillations with the plasma frequency ω_p .

In addition to the electric field, the electrons are driven by a gradient in electron pressure, in density, in the local Fermi energy proportional to $(n_0)^{2/3}$. This pressure spreads out the electrons at metal surfaces and metal-metal interfaces leading to surface dipoles and contact potentials. In the Drude model, this additional force can be introduced by a term $-\beta \nabla \rho$:

$$\frac{\partial \mathbf{j}}{\partial t} = \omega_p^2 \varepsilon_0 \mathbf{E} - \gamma \mathbf{j} - \beta \nabla \rho \quad [42]$$

The coefficient $\beta = (3/5)v_F^2$ in a free electron gas with Fermi velocity v_F . The expression for the high-frequency electron gas pressure was derived by Bloch. Equation [42] can be derived from a Boltzmann equation for the electron gas, and it is called the "hydrodynamic approximation" to a quantum mechanical treatment of the free electron gas. This extended Drude model describes plasma waves and makes it easy to include them in metal optics in the correct way.

First, the plasma waves are seen as eigensolutions of the system. Equation [41] is now supplemented to yield

$$\rho = -\omega_p^2 \rho - \gamma \dot{\rho} + \beta \nabla \cdot (\nabla \rho) \quad [43]$$

which is solved by a wave with the plasmon dispersion [40] when the damping γ is neglected. The mode is a charge density wave (analog to a longitudinal acoustic density wave) with longitudinal electric fields $E \parallel \mathbf{k}$. Transverse waves have necessarily $\rho=0$ from eqn [9]. Therefore, the response, conductivity $\sigma_\perp$ and $\varepsilon_\perp$, is not affected by the new term in [42], and remains as in eqns [30] and [31]. But the longitudinal response is changed. For a plane wave perturbation $\sim e^{i(\mathbf{k}\mathbf{r}-\omega t)}$, the continuity equation $(1/i\omega)\nabla \cdot \mathbf{j} = \rho$ replaces ρ in eqn [42], and for longitudinal fields and currents,

$$\sigma_\parallel(k, \omega) = \frac{i\omega\omega_p^2\varepsilon_0}{\omega^2 - \beta k^2 + i\omega\gamma} \quad [44]$$

and with the general relation [13]:

$$\varepsilon_\parallel(k, \omega) = 1 - \frac{\omega_p^2}{\omega^2 - \beta k^2 + i\omega\gamma} \quad [45]$$

The response functions are now dependent on frequency ω and wave vector $\mathbf{k}$. This is the so-called nonlocal response (in time and now also in space), which is familiar in nonlocal metal optics.

What do Maxwell's equations tell one about longitudinal waves? Equation [3] shows that longitudinal plasma waves have no magnetic induction field, $\mathbf{B}=0$. On the other hand, the longitudinal wave is a homogeneous solution of the wave equation [12]:

$$\nabla(\nabla \cdot \mathbf{E}) - \Delta \mathbf{E} = \frac{\omega^2}{c^2} \mu \varepsilon_\parallel \mathbf{E} \quad [46]$$

For a wave with $E \parallel \mathbf{k}$, the left-hand side is zero and a nontrivial solution requires the general dispersion relation for plasmons

$$\varepsilon_\parallel(k, \omega) = 0 \quad [47]$$

With eqn [45], neglecting the damping γ , [47] yields [40]. The hydrodynamic approximation (eqns [42], [44], and [45]) should be considered as the long wavelength, small k expansion of any sophisticated treatment of conduction electron response. For the

purpose of optics, this approximation has been shown to be sufficient for the analysis of many experiments involving metal surfaces or metal layers at frequencies around the plasma frequency.

The longitudinal plasma waves are homogeneous solutions of Maxwell's equations according to eqn [46], and must therefore be included in the general solutions, which via boundary conditions yield the optical fields. Sauter was the first to point this out in 1964, and he suggested the third boundary condition, which is necessary at a free metal surface to determine the three amplitudes: of the reflected wave R (eqn [17]) and inside the metal of the transmitted transversal wave T (eqn [18]) and of the longitudinal wave $Le^{i(k_z x + \eta z)}$, which completes the general solution [18].

Before the boundary conditions are discussed, the question of energy current is addressed. When it was brought up that the longitudinal waves should be excited on reflection at metal surfaces, it was objected that this additional channel of energy transport would have long been recognized if the suggestion was true. The wrong answer is that the plasma wave does not carry energy, because $\mathbf{B}=0$ and therefore, the Poynting vector $\mathbf{S}=0$. But the excitation of plasma waves becomes appreciable for frequencies of the order ω_p , which is in the UV where hardly any reflection measurements have been done. In addition, the energy current of the plasma wave is small because of the very small group velocity of plasmons:

$$\frac{\partial \omega}{\partial k} \approx \beta \frac{k}{\omega_p} \sim \frac{v_F^2}{c} \quad [48]$$

The extension of the material equation [42] leads to an extension of Poynting's theorem: By taking the dot product of eqn [3] with H and subtracting the dot product of E with eqn [3], one obtains

$$-\frac{\partial}{\partial t} \left(\frac{1}{2} E \cdot D + \frac{1}{2} H \cdot B \right) = \nabla \cdot (E \times H) + E \cdot j \quad [49]$$

Multiplying the material equation of motion [42] by j , the terms can be rearranged with the help of the continuity equation

$$\omega_p^2 \epsilon_0 E \cdot j = \frac{\partial}{\partial t} \left(\frac{1}{2} j^2 \right) + \gamma j^2 + \nabla \cdot (\beta \rho j) + \frac{\partial}{\partial t} \left(\frac{1}{2} \beta \rho^2 \right) \quad [50]$$

which by replacing $E \cdot j$ in eqn [49] yields Poynting's theorem with plasma waves:

$$-\frac{\partial}{\partial t} \left(\frac{1}{2} E D + \frac{1}{2} H B + \frac{1}{2 \omega_p^2 \epsilon_0} j^2 + \frac{1}{2 \omega_p^2 \epsilon_0} \beta \rho^2 \right) = \nabla \cdot (E \times H + \frac{1}{\omega_p^2 \epsilon_0} \beta \rho j) + \frac{\gamma}{\omega_p^2 \epsilon_0} j^2 \quad [51]$$

On the left-hand side, the kinetic energy density of the electron current and the potential energy density connected with the density perturbation against the electron gas pressure are found. On the right-hand side, one has the energy current density in the plasma wave and the positive definite energy absorption due to the friction coefficient γ .

The problem of "additional boundary conditions" is taken up next. At first, the total response is described by ρ and j , that is, formally $\chi_p=0, P=0$. It has been mentioned already after eqn [21] that the standard boundary conditions, $D_{\text{eff},n}$ and H_{tg} continuous, imply a discontinuity in E_n caused by singular surface charges, and from eqn [8], the denial of singular surface currents. With $j=\sigma \cdot E$, one also gets a finite normal component of the current up to the surface, which then disappears in a singular sink or source of charge in the surface plane. In nonlocal optics, the charges and currents are treated seriously in the plasma waves, and especially singular charges would lead to infinite pressures in eqn [42]. The model of the surface must be improved. Singular surface charges can only be avoided if the normal component of the current j is continuous (zero at a free surface). With finite charge densities everywhere, the normal component of E is also continuous. These two independent conditions replace the continuity of $D_{\text{eff},n}$, which is then a consequence. Continuous E and continuous D_{eff} does not contradict eqn [13], because σ and ϵ are now tensors with $\epsilon_{\perp} \neq \epsilon_{\parallel}$.

At an interface with metal only on one side, one has one reflected wave amplitude in the dielectric, and a transverse and a longitudinal wave amplitude in the metal to be determined via three boundary conditions:

$$(a) \text{ continuity of } E_{\text{tangential}} \quad [52]$$

$$(b) \text{ continuity of } E_{\text{normal}} \quad [53]$$

$$(c) j_{\text{normal}} = \sigma_{\perp} E_{\perp \text{normal}} + \sigma_{\parallel} E_{\parallel \text{normal}} = 0 \quad [54]$$

For the interface between two metals, a fourth amplitude via a fourth boundary condition must be determined because there are plasma waves in both metals. A reasonable requirement is that the interface should not be a singular sink or source of energy. This plausible assumption for our surface model leads to the continuity of the normal component of the energy current; so the boundary conditions at a metal-metal interface are

$$(a) \text{ continuity of } E_{\text{tangential}} \quad [55]$$

$$(b) \text{ continuity of } E_{\text{normal}} \quad [56]$$

$$(c) \text{ continuity of } j_{\text{normal}} = \sigma_{\perp} E_{\perp \text{normal}} + \sigma_{\parallel} E_{\parallel \text{normal}} \quad [57]$$

$$(d) \text{ continuity of } \frac{\beta}{\omega_p^2 \epsilon_0} \rho = \frac{\beta}{\omega_p^2} \nabla \cdot \mathbf{E} = \frac{\beta}{\omega_p^2} \mathbf{k}_{\parallel} \cdot \mathbf{E}_{\parallel} \quad [58]$$

The conductivity $\sigma_{\perp}$ for transverse fields is also from eqn [42] equal to eqn [30], and $\epsilon_{\perp}$ is given by eqn [31]. With (a), (b), and (c), the Poynting vector is continuous; so the requirement [58] suffices to make the total normal energy current continuous. All boundary conditions lead to linear equations for the determination of the reflection and transmission amplitudes, therefore to no complication, in principle, compared to standard optics.

In this treatment of plasma waves in optics, the response functions $\sigma_{\parallel}$ and $\epsilon_{\parallel}$ are dependent on frequency ω as well as on wave vector k or wavelength; hence, this kind of optics is called nonlocal optics. Equation [42] says that the current at r is not only driven by the electric field at r (local relation), but the charge density in the neighborhood determines the other force $\sim \nabla_{\rho}$. Charge density waves with larger gradients, larger k , oscillate faster according to eqn [40]. The standard local optics is an approximation which neglects charge densities altogether and does not treat the singular surface charges consistently which eqn [21] implies. This standard approximation is simpler and sufficient as long as the charge densities are small. At frequencies of the order of the plasma frequency, the charge densities get large due to resonant eigenmodes and must be treated consistently. The nonlocal optics can lead to results qualitatively different from standard optics and in agreement with the experiment.

A few examples of this nonlocal metal optics are discussed next. One can understand at the beginning that only when there are normal components of $\mathbf{E}$, normal currents leading to oscillating charge densities near the surface, a plasma wave is optically excited. Therefore, only for p -polarization with the electric field parallel to the plane of incidence, this nonlocal extension of optics is necessary, and the plasmon gets a nonzero amplitude L .

In the case of reflection from a free metal surface, the extension of the treatment in eqns [17]–[23] takes the steps: the outgoing general solution [18] inside the metal is supplemented by the plasma-wave $+Le^{i(k_x x + \eta z)}$ with η from

$$\epsilon_{\parallel} = 0 = 1 - \frac{\omega_p^2}{\omega^2 - \beta(k_x^2 + \eta^2) + i\omega\gamma} \quad [59]$$

and with

$$\eta = \sqrt{\frac{1}{\beta} [\omega(\omega + i\gamma) - \omega_p^2] - k_x^2} \quad [60]$$

and for the longitudinal wave

$$L_x/L_z = k_x/\eta \quad [61]$$

The three boundary conditions [52]–[54] lead to three linear equations and to the reflection amplitude

$$\frac{R_z}{E_{0z}} = \frac{\epsilon_{\perp} q - l + (\epsilon_{\perp} - 1)k_x^2/\eta}{\epsilon_{\perp} q + l - (\epsilon_{\perp} - 1)k_x^2/\eta} \quad [62]$$

with $\epsilon_{\perp} = \epsilon_M$ and q, l from eqns [31], [19], and $\epsilon_1 = 1, \mu_M = \mu_1 = 1$. The limit $\beta \rightarrow 0$ leads back from [42] to local [28], in [60] to $\eta \rightarrow \infty$, and from [62] back to [22]. The difference between $r = |R_z/E_{0z}|^2$ from [62] and from [22] is shown in Figure 2. The excitation of plasma waves really reduces the reflectivity, but only above the plasma frequency and by a small amount. This case was outlined to demonstrate that this extension of metal optics is straightforward.

As in the previous section, one finds from the zero of the denominator of the reflection amplitude [62], the dispersion relation of the surface plasmon polariton

$$\epsilon_{\perp} q + l - (\epsilon_{\perp} - 1)k^2/\eta = 0 \quad [63]$$

For low frequencies, the last term of the order of $k(v_F/\omega_p)$ can be neglected and the dispersion agrees with [35]. But for $k \approx (\omega/c)(c/2\sqrt{\beta})^{1/3}$, the frequency of the eigensolution [63] rises above $\omega_p/\sqrt{2}$, which was the limit for [35]. The approximate dispersion in this frequency range is from eqn [63]:

$$\omega_s \approx \frac{\omega_p}{\sqrt{2}} + k \frac{\sqrt{\beta}}{2} \quad [64]$$

This linear dispersion is often extrapolated toward $k=0$. In optics, this is wrong because then, the light line is crossed and light could couple to the eigenmodes which is not the case. For larger k , the increase of ω_s is stronger than linear which is indicated in Figure 2. This dispersion describes the essential facts of the experiments. Only the linear rise [64] is usually suppressed to a plateau due to a skin effect before the final rise, when at large k the electron gas pressure dominates.

The dispersion relation [64] was derived when Ritchie discovered this surface mode in 1957 from an electrostatic approximation to Maxwell's equations ($c \rightarrow \infty$) and called it the surface plasmon. When the charge densities in the plasma and Maxwell's equations

Figure 2 The reflectivity r with plasma waves, r_{Fr} standard Fresnel formula.

are treated correctly, it becomes clear that [35] and [64] are approximations to the dispersion [63] of a single kind of surface mode, which is then properly termed the “surface plasmon polariton” (SPP).

The reflection from a simple metal surface is changed so little by the inclusion of plasma waves in optics (Figure 2) that this is not the experiment to prove the necessity of nonlocal optics. The first relevant experiment was theoretically predicted by Melnyk and Harrison in 1968 and carried out by Lindau and Nilson in 1970. The transmittance through thin silver layers shows periodic minima when the plasma waves form standing waves in the layer and by the large amplitude, increase the absorption. It turns out that half a wavelength and even three and five halves of a wavelength fit into a layer of 100 Å. One can calculate from eqn [40] that this is the order of the plasma wavelength, while the transverse waves are more than ten times longer, so the experiment can only be explained by the optical excitation of plasma waves in the metal. Another example is shown in Figure 3. An electroreflection experiment measures the change in reflectivity $\Delta r/r$ when a strong (static or slowly oscillating) electric field changes the charge density at the metal surface. The optical calculations give qualitatively different results when standard local optics or nonlocal optics is employed. Only nonlocal optics describes the experiment. In the late 1970s and early 1980s, several examples were published with the same outcome (see the “Further reading” section.)

One can draw the general conclusions: standard optics must be extended to nonlocal optics when the optical frequency ω is around the plasma frequency ($0.5\omega_p < \omega < 2\omega_p$) and when metallic layers, especially very thin ones (1–1000 Å), are involved. The nonlocal optics discussed in this article gives the right answers in these cases.

The treatment of plasma waves in optics in this section is designed for a free electron gas model of a metal, where the total response can be described as conduction electron current density and charge density. The parameters, electron density n_0 and damping γ , could be taken from a fit of a model (eqn [31]) to measure dielectric data. This is a good approximation for most metals except the d -band transition metals. But silver is one of the best candidates for demonstrating the effects of nonlocal optics because its plasma frequency is easily accessible just above the visible at $\hbar\omega_p = 3.8$ eV and the plasmons see little damping. The conduction electron density in silver is high and would lead to $\hbar\omega \approx 9$ eV from eqn [29]. $\epsilon=0$ is shifted to a lower frequency because of other “bound” electrons.

In such a situation, it has been successful to think of two responding electron systems, free and bound. The free conduction electrons follow eqn [42] while the bound ones are described by a polarizability χ_p . The total measured ϵ is then separated as in eqn [13]. An assumption of the conduction electron density (and the damping) allows the determination of χ_p from [13]. Then it is consistent to use in [53] and [56] the normal component of $D = (1 + \chi_p)\epsilon_0 E$. This procedure was used for Figure 3 and for many other comparisons with experiments on silver.

A final remark shall close this section: the response of a metal to electromagnetic fields is a vast field in solid-state theory where quite a number of theoreticians have invested their ingenuity. Here, a simple extension of standard optics was presented which can easily be applied by experimentalists also and has been successfully used for the analysis of several experiments. Around the plasma frequency, the predictions of nonlocal optics including plasma waves can be qualitatively different from the results of standard optics.

Magneto-optics

The response of metals as well as other materials to electromagnetic waves is determined by the forces due to the electric field of the wave, because the Lorentz force due to the magnetic field is weaker by a factor $v/c < 1\%$ with electron velocity of the order of the Fermi velocity. Magneto-optics considers the interaction of light with external magnetic fields or strong magnetizations in ferromagnets.

A system with a magnetic field or magnetization acquires a special symmetry with respect to time inversion ($E, B, H, M \rightarrow E, -B, -H, -M$). Onsager's relations require

$$\varepsilon_{ij}(E, B, H) = \varepsilon_{ji}(E, -B, -H) \quad [65]$$

Therefore, optical effects introduced by (proportional to) B or M manifest themselves as antisymmetric tensor components in an otherwise symmetric dielectric tensor $\hat{\varepsilon}$.

It is briefly shown that an external magnetic field leads to antisymmetric ε -components in an extension of the Drude model (eqns [27] and [28]) and that the consequence in optics is a difference in index of refraction for right and left circularly polarized waves. This leads to the Faraday rotation of the plane of polarization for linearly polarized light in transmission and to the Kerr rotation in reflection.

The Lorentz force $-e_0(\dot{\mathbf{r}} \times \mathbf{B}_0)$, in an external magnetic field $\mathbf{B}_0 = (0, 0, B_0)$ parallel to the z -axis, is added to the equation of motion [27]. To be more general, an elastic restoring force $-\omega_0^2 \mathbf{r}$ is also added (for free electrons in metals $\omega_0 \rightarrow 0$):

$$m\ddot{\mathbf{r}} = -e_0 E - m\gamma \dot{\mathbf{r}} - m\omega_0^2 \mathbf{r} - e_0(\dot{\mathbf{r}} \times \mathbf{B}_0) \quad [66]$$

With $\mathbf{r} \sim \exp(-i\omega t)$ and $\mathbf{j} = -e_0 n_0 \dot{\mathbf{r}}$, one finds from [66] the conductivity tensor and obtains from eqn [13] the dielectric tensor:

$$\hat{\varepsilon} = \hat{1} + \omega_p^2 \begin{pmatrix} a & ib & 0 \\ -ib & a & 0 \\ 0 & 0 & c \end{pmatrix} = \varepsilon \begin{pmatrix} 1 & iQ & 0 \\ -iQ & 1 & 0 \\ 0 & 0 & \alpha \end{pmatrix} \quad [67]$$

$$a = \frac{\omega_0^2 - \omega(\omega + i\gamma)}{(\omega_0^2 - \omega(\omega + i\gamma))^2 - \omega^2 \omega_c^2} \quad b = \frac{\omega \omega_c}{(\omega_0^2 - \omega(\omega + i\gamma))^2 - \omega^2 \omega_c^2} \quad [68]$$

$$c = \frac{1}{\omega_0^2 - \omega(\omega + i\gamma)} \quad [69]$$

$\omega_c = eB_0/m$ is the cyclotron frequency proportional to B_0 . Due to the external magnetic field, one finds an antisymmetric tensor added to an otherwise symmetric $\hat{\varepsilon}$.

The dielectric tensor is now employed on the right-hand side of the wave equation [12]. For a wave traveling in the z -direction parallel to B_0

$$\begin{aligned} \left(\frac{\omega^2}{c^2} \varepsilon - k^2\right) E_x + iQ\varepsilon \frac{\omega^2}{c^2} E_y &= 0 \\ -iQ\varepsilon \frac{\omega^2}{c^2} E_x + \left(\frac{\omega^2}{c^2} \varepsilon - k^2\right) E_y &= 0 \end{aligned} \quad [70]$$

$$\left(\frac{\omega^2}{c^2} \varepsilon (1 \pm Q) - k^2\right) (E_x \pm iE_y) = 0 \quad [71]$$

which yields

$$\begin{aligned} k_r^2 &= \frac{\omega^2}{c^2} \varepsilon (1+Q) \quad \text{for } E_x = iE_y \\ (\text{for right circular polarized light}) \\ k_l^2 &= \frac{\omega^2}{c^2} \varepsilon (1-Q) \quad \text{for } E_x = -iE_y \\ (\text{for left circular polarized light}) \end{aligned}$$

or

$$n_r = \sqrt{\varepsilon} \left(1 + \frac{1}{2}Q\right) \quad \text{and} \quad n_l = \sqrt{\varepsilon} \left(1 - \frac{1}{2}Q\right) \quad [72]$$

The increase of the effective ε or polarizability for right circular polarization can be understood for the simple model (eqn [66]) from the direction of the Lorentz force which increases the radius of the circular electron motion. When light travels through a piece of matter of length L , the waves accumulate a phase difference of

$$\delta = (k_l - k_r)L = \frac{\omega}{c} L(n_l - n_r) = \frac{\omega}{c} LQ \quad [73]$$

The Faraday rotation of the plane of linear polarization is $\delta/2$. Because Q is proportional to ω due to the Lorentz force, the Faraday rotation is proportional to ω^2 .

Generalizations

The dielectric tensor is more generally expressed as

$$\hat{\varepsilon} = \varepsilon \begin{pmatrix} 1 & iQ_z & -iQ_y \\ -iQ_z & 1 & iQ_x \\ iQ_y & -iQ_x & 1 \end{pmatrix} \quad [74]$$

by the “Voigt vector” $Q = (Q_x, Q_y, Q_z)$.

Then in the refraction indices (eqn [72]), Q is generalized: $Q \rightarrow Q\mathbf{k}/|k|$, to the projection of Q on the direction of propagation $\mathbf{k}$. In the model and in transparent materials, Q is mainly real and one finds the Faraday rotation due to the real phase shift (eqn [73]). In ferromagnetic metals, the magneto-optical effects are larger by several orders of magnitude, but here, mainly the absorption, the imaginary part of Q is changed by the magnetization leading to elliptically polarized light in general.

Because ferromagnetism is rooted in the electron spin, a microscopic explanation of the magneto-optical effects in ferromagnets involves the spin-orbit coupling of the electron motion and the unequal number of spins parallel and antiparallel to M .

For the investigation of magnetic properties of metallic layers, the magneto-optical Kerr effect (MOKE) in reflection has been developed into an efficient tool. With strong lasers, nonlinear optical response is also exploited (for detailed information see the “Further reading” section).

“Left-Handed Materials,” Optics for $\varepsilon < 0$ and $\mu < 0$

Charge carriers exposed to oscillating electric fields show, in some frequency region, negative polarizability as a forced oscillator has a phase shift of π above resonance. Therefore, in simple metals $\varepsilon < 0$ below the plasma frequency (resonance frequency $\omega_0 \rightarrow 0$) (eqns [31] and [32]). Then the index of refraction $n = \sqrt{\varepsilon}$ is imaginary, electromagnetic waves decay exponentially into the metal, do not propagate at all and the reflectivity goes to 1.

In 1968, V G Veselago pointed out that the wave propagation is really determined by the product $\varepsilon\mu$ (eqns [16] and [19]) and therefore, a system with $\varepsilon < 0$ and $\mu < 0$ in the same frequency region would be transparent again. One has, in principle, negative

Figure 4 Refraction at a left-handed material.

magnetic polarizability in diamagnets (due to Lenz's rule) but usually the polarizabilities χ_m are extremely small ($\sim 10^{-6}$), and the susceptibility $\mu = 1 + \chi_m$ deviates little from 1 and does not go below 0.

Recently materials with $\mu < 0$ have been manufactured. Therefore, the surprising optical properties are outlined. The term "left-handed material" (LHM) derives from the fact that Maxwell's equations (e.g., (eqn [3])) for a plane wave $\mathbf{k} \times \mathbf{E} = \omega \mathbf{B}$ and $\mathbf{H} = (1/\mu_0\mu)\mathbf{B}$ usually make the vectors $\mathbf{k}, \mathbf{E}, \mathbf{H}$ a right-handed tripod, while with $\mu < 0$ the tripod gets left-handed. Consequently, normally the energy current $\mathbf{S} = \mathbf{E} \times \mathbf{H}$ is parallel to the wave vector $\mathbf{k}$. In LHMs, the Poynting vector is opposite to $\mathbf{k}$.

Refraction at an interface between material I ($\epsilon_I > 0, \mu_I > 0$) and material II ($\epsilon_{II} < 0, \mu_{II} < 0$) puts the refracted beam in II on the opposite side of the surface normal than usual. Therefore, diverging rays in I can converge in II which led to speculations about perfect lenses by slabs of LHMs. This uncommon refraction can be understood as follows:

$\mathbf{S} = \mathbf{E} \times \mathbf{H}$ is antiparallel to $\mathbf{k}$ in LHM II. Therefore, the correct homogeneous solution in II which carries the energy from the interface has a wave vector pointing towards the interface. The tangential components of all wave vectors are equal, so the refracted beam (i.e., the energy current) lies in II on the same side of the surface normal as the incoming beam in I (see Figure 4).

The subject of optics with LHMs has been revived after 2000 in connection with the investigation of the "optical" properties of conducting networks, three-dimensional wire mesh crystals. If the wavelength of the electromagnetic waves are much larger than the lattice spacing, the conducting network behaves like a metallic conductor with a low density plasma frequency and with a frequency region of negative ϵ according to eqn [32]. The necessary large diamagnetism is achieved by conducting rings in each cell of the lattice. In such a designed material, $\epsilon < 0$ and $\mu < 0$ at frequency $\nu = 10.5$ GHz, $\lambda \approx 3$ cm, was demonstrated with $\epsilon\mu = 7.28 \pm i0.54$. It was shown that the refraction is indeed as in Figure 4 (see the "Further reading" section).

ω_v	vibrational mode with angular frequency

Introduction

The propagation of optical waves inside a medium is described by the wave equation:

$$\nabla^2 E = \frac{1}{c^2} \frac{\partial^2 E}{\partial t^2} + \mu_0 \frac{\partial^2 P}{\partial t^2} \quad [1]$$

where $E(\mathbf{r}, t)$ is the electric field and $P(\mathbf{r}, t)$ is the macroscopic polarization. Traditional optics is based on the simplified assumption that P is linearly related to E through a differential equation describing the noninstantaneous response of the medium. In the frequency domain, $P(\mathbf{r}, \omega) = \epsilon_0 \chi(\omega) E(\mathbf{r}, \omega)$, where $E(\mathbf{r}, \omega)$ and $P(\mathbf{r}, \omega)$ are the electric field and polarization Fourier transforms, and $\chi(\omega)$ is the frequency-dependent electric susceptibility that is related to the index of refraction of the material through the expression: $n(\omega) = \sqrt{1 + \chi(\omega)}$. Actually the relation between P and E is intrinsically nonlinear and can be considered approximately linear when the optical field is much smaller than the internal field seen by the electron. Whereas in the past the optical intensities available with conventional sources were too weak to explore optical nonlinearities, it is now very easy to generate nonlinear optical effects by exploiting laser beams. The term nonlinear optics should apply to all the physical situations in which the linear approximation is not adequate. This article is limited to a treatment of those nonlinear optical interactions that are nonresonant. Resonant interactions, such as those responsible for laser behavior, optical bistability, or electromagnetically induced transparency, are discussed elsewhere in this encyclopedia.

Nonlinear optics has enhanced the understanding of fundamental light-matter interactions and provided new powerful methods for the investigation of materials. At the same time, nonlinear optics has a strong impact on technology as it offers the way to develop coherent radiation sources, emitting at new frequencies that are not usually available with lasers, and offering tunability from ultraviolet to visible and near infrared. Important applications also concern optical devices performing the same functions provided at radio frequencies by electronic devices, such as modulators, switches, and logical circuits.

Physical Origin of Nonlinearity

A simple physical model describing the relation between P and E is represented by the Lorentz model that treats a bound electron as a harmonic oscillator. Clearly, the assumption that the electron is in a parabolic potential well is valid only for small displacements from the equilibrium position. As shown in Figure 1, if the exciting field is strong enough, the electron displacement will also probe a range of distances over which the potential is no longer parabolic. The potential can be written as a Taylor expansion in the displacement x : $V(x) = V_0 + \alpha x^2 + (1/2)\beta x^3 + (1/3)\gamma x^4 + \dots$. It can be easily seen by a perturbative approach that the cubic term in $V(x)$ can give rise to a polarization term proportional to the square of the field, and the quartic term gives a term proportional to the cube of the field.

Note that a cubic term in $V(x)$ can exist only if the material structure is not centrosymmetric, as it happens with a crystal having a noncentrosymmetric unit cell or a system of oriented polar molecules. On the macroscopic scale the relation between $P(\mathbf{r}, \omega)$ and $E(\mathbf{r}, \omega)$ can be written as

$$P = \epsilon_0 \chi^{(1)} E + \epsilon_0 \chi^{(2)} E^2 + \epsilon_0 \chi^{(3)} E^3 + \dots \quad [2]$$

Materials presenting a second-order nonlinearity, when illuminated with a beam at angular frequency ω , can generate a second-harmonic beam at frequency 2ω . If two beams at frequencies ω_1 and ω_2 are sent into the material, a third beam at the sum or difference frequency $\omega_3 = \omega_1 \pm \omega_2$ can be generated. Such a process is used in optical parametric amplifiers and oscillators. In the case of third-order materials, besides the generation of new frequencies through various frequency-mixing processes,

Figure 1 Particle motion in an asymmetric potential well under the action of a sinusoidal field: the oscillation is not symmetric; thus, it contains higher-harmonic contribution.

phenomena such the optical Kerr effect, self-focusing, self-phase modulation, and optical phase-conjugation can be observed and exploited for the realization of optical devices. In addition, stimulated Raman and Brillouin scattering also belong to the family of third-order effects.

Second-Order Nonlinear Effects

Second-Harmonic Generation

In order to illustrate the basic aspects of nonlinear interactions, it is better to start with the simplest situation: a second-order material illuminated by a monochromatic plane wave propagating along the z -axis $-E_1 \exp[i(\omega_1 t - k_1 z)]$. It is easy to see from eqn [2] that such a wave gives rise to a nonlinear polarization oscillating at $2\omega_1$. In turn, the nonlinear polarization, once inserted into eqn [1], behaves like a source for a second-harmonic (SH) optical wave. Limiting the consideration to stationary waves in the slowly-varying-envelope-approximation and expressing the pump and SH fields E_1 and E_2 as $E_1 = A_1(z)\exp(ik_1 z)$ and $E_2 = A_2(z)\exp(ik_2 z)$, respectively, the evolution of the SH generation phenomenon can be described through the following equations:

$$\begin{aligned}\frac{d}{dz} A_1(z) &= i \frac{\omega_1}{cn_1} d_{\text{eff}} A_2(z) A_1^*(z) \exp(-i\Delta k z) \\ \frac{d}{dz} A_2(z) &= i \frac{\omega_1}{cn_2} d_{\text{eff}} A_1^2(z) \exp(i\Delta k z)\end{aligned}\quad [3]$$

where $d_{\text{eff}} = \chi^{(2)}/2$ is called the effective nonlinear coefficient, $\Delta k = k_2 - 2k_1$ is the wave vector mismatch, c is the light velocity, and n_1 and n_2 represent the refractive indices experienced by the pump and SH fields during the propagation through the nonlinear medium. It is important to remark that, in scientific literature, the nonlinear properties of materials are usually expressed in terms of the d_{eff} coefficient values. It can be seen from eqns [3] that the condition for efficient SH generation is: $\Delta k = 0$. Such a condition is called the phase-matching condition. It expresses the requirement that the nonlinear polarization wave travels at the same phase velocity as the SH wave. It should be noted that the process consists in an exchange of energy (and momentum) between waves in which the nonlinear medium acts as a catalyst. If the process is described by a quantum-mechanical approach, two photons of the fundamental wave are converted into an SH photon; the phase-matching condition corresponds to momentum conservation in the nonlinear process.

In the case $\Delta k = 0$, the propagation equations can be solved analytically, giving the SH intensity as a function of the propagation distance z :

$$I_2(z) = I_1(0) \tanh^2(z/L_{\text{SH}}) \quad [4]$$

where the constant L_{SH} is inversely proportional to the nonlinear coefficient of the medium and to the square root of the input intensity. Equation [4] shows that the input intensity can be fully converted into the SH provided that the propagation distance is sufficiently long (the crystal length L should be larger than L_{SH}). As an example, by using a lithium niobate crystal with a second-order coefficient $d_{\text{eff}} = 5 \text{ pm V}^{-1}$ and a neodymium laser ($\lambda = 1064 \text{ nm}$) beam with an intensity of 10 MW cm^{-2} , $L_{\text{SH}} = 1 \text{ cm}$. When the phase-matching condition is not satisfied, $I_2(z)$ is an oscillating function of z (see Figure 2): the SH intensity achieves a maximum after a distance called coherence length $l_c = \pi/\Delta k$ and vanishes at $z = 2l_c$.

Figure 2 SH intensity as a function of propagation distance in a nonlinear crystal.

Figure 3 Scheme of an SH laser: mirrors 1 and 2 have high reflectivity for the frequency ω corresponding to the laser transition, but are transparent for 2ω .

SH generation of a laser beam becomes particularly efficient if the nonlinear crystal is placed inside a laser cavity (see Figure 3). At present, such an approach represents one of the most convenient methods of generating coherent green and blue light by using near infrared solid-state lasers. As an example, a 532 nm green light is efficiently generated by intracavity frequency doubling of a neodymium laser.

Phase Matching

Recalling that the modulus of k is related to the angular frequency by the relation $k = (\omega/c)n(\omega)$, the phase-matching condition $\Delta k = 0$ requires that the index of refraction of the second harmonic be equal to that of the fundamental. In normal cases, n is an increasing function of frequency, so that phase matching is not satisfied for beams having the same polarization. A very clever method of obtaining phase matching is that of exploiting the crystal birefringence to compensate for the material dispersion (see Figure 4). Recall that, in a crystal possessing an optical axis, the propagation velocity of a linearly polarized plane wave depends on its polarization direction: a wave polarized perpendicularly to the optical axis sees the “ordinary” index of refraction n_o , whereas a wave polarized along the optical axis sees the “extraordinary” index n_e . A typical nonlinear crystal is lithium niobate, a uniaxial crystal presenting negative birefringence, that is, $n_o > n_e$. It can be shown that there is a frequency ω_{pm} for which $n_o(\omega_{pm}) = n_e(2\omega_{pm})$. In such a situation, an ordinary input beam at frequency ω_{pm} , propagating perpendicularly to the optical axis, can be efficiently converted into an extraordinarily polarized SH beam. Noting that the index of refraction of the extraordinary beam can be changed continuously between n_o and n_e by changing the angle θ between k and the optical axis, ω_{pm} can be tuned by appropriately rotating the crystal.

Since the indices of refraction depend on temperature, it is possible to tune ω_{pm} finely by varying T . More degrees of freedom are added to the SH experiment if two input beams having the same frequency, but different direction or different polarization, are considered.

From the point of view of applications, a very important trend that emerged in recent years is that of considering nonlinear interactions in microstructured materials and in waveguides. It goes beyond the scope of this article to approach such a subject; however, mention may be made here that a microstructured material, in which the value of the $\chi^{(2)}$ coefficient varies with a spatial periodicity Λ , can exchange momentum with the propagating waves in multiples of the unit $2\pi/\Lambda$, so that, in principle, phase matching can be achieved at any desired frequency by appropriately choosing the period Λ (see Figure 5). Concerning waveguided

Figure 4 Birefringence phase matching.

Figure 5 Periodically poled ferroelectric crystal presenting a uniform $\chi^{(1)}$ and an oscillating $\chi^{(2)}$.

propagation, the main difference with respect to bulk propagation is that the waveguide can support different spatial modes possessing different phase velocities even if they have the same frequency; such a “modal dispersion” also opens new possibilities of phase matching.

This section concludes with an important consideration: whereas the “ideal” phase-matching condition is $\Delta k = 0$, the “practical” condition in a crystal of finite length L is $\Delta k L < \pi$, or, equivalently, $l_c > L$. As a consequence, there is a frequency interval, centered on ω_{pm} , in which efficient SH generation can be achieved. The existence of a nonzero spectral acceptance makes it possible to use short pulses, instead of stationary beams, in nonlinear optical experiments.

Parametric Amplification and Oscillation

If two beams, possessing different frequencies ω_1 and ω_2 , and different wave vectors $\mathbf{k}_1$ and $\mathbf{k}_2$, are sent into a second-order nonlinear crystal, the nonlinear polarization can give rise to new frequencies representing the SH of each beam or the sum/difference of the input frequencies. By choosing a specific phase-matching condition, only one process is selected among all possible processes. If the difference-frequency generation (DFG) is selected, and it is assumed that $\omega_1 > \omega_2$, a new beam at frequency $\omega_3 = \omega_1 - \omega_2$ and wave vector $\mathbf{k}_3$ is obtained, provided that the condition $\mathbf{k}_3 = \mathbf{k}_1 - \mathbf{k}_2$ is satisfied (see Figure 6).

Figure 6 Tuning curves for an optical parametric oscillator pumped by the third- and fourth-harmonic of a neodymium laser. (Reproduced with permission from Cheng *et al.* (1988) *Applied Physics Letters* 53(3): 175–177.)

Figure 7 Comparison between the three-level laser, using real energy levels, and the optical parametric oscillator, using virtual levels.

All the phase-matching methods discussed in the previous section in connection with SH generation can also be applied to the sum/difference frequency generation. By using the same approach outlined for SH generation, it is easy to derive nonlinear propagation equations for the sum/difference fields having a structure similar to that of eqns [3]. In the DFG process, one photon at frequency ω_1 is annihilated and two photons at frequencies, respectively ω_3 and ω_2 , are created, so that the process not only produces a new coherent beam at ω_3 , but also amplifies the beam at ω_2 . Such an amplification process is called parametric amplification. Whereas standard optical amplifiers work only at frequencies corresponding to transitions among energy levels, parametric amplifiers use transparent crystals and can work, in principle, over the whole transparency window of the crystal, provided that phase matching can be achieved (see Figure 7).

Recalling that an optical amplifier can become a laser oscillator once inserted into an optical cavity, a similar approach can transform the parametric amplifier into a parametric oscillator. Whereas in the laser case, the trigger to cavity oscillation comes from spontaneous emission from the upper level of the amplifying medium, the initial seed for parametric oscillation comes from parametric fluorescence, the process by which the “pump” photon at frequency ω_1 spontaneously breaks down into two photons at frequencies ω_2 (signal) and ω_3 (idler). Potentially, parametric fluorescence can yield any couple of frequencies satisfying energy conservation, the choice among all possible couples being determined by the phase-matching condition. The tuning of the parametric oscillator is generally achieved by rotating the crystal or by changing the operating temperature.

Nonlinear Optical Materials

The second-order processes described in the previous sections require the availability of noncentrosymmetric media. Such media are intrinsically anisotropic, so that the electric susceptibilities become tensorial quantities. In particular, $\chi^{(2)}$ is a third-order tensor, possessing 27 components χ_{ijk} . This fact makes the description of beam propagation inside the crystal and also the search for phase matching conditions rather complicated. Such descriptions are beyond the scope of this article; however, the following example is taken up: consider an input field polarized along the x -axis (this implies $j = k = 1$); birefringence phase matching requires that the generated nonlinear polarization lies along the z -axis (this implies $i = 3$), so that the useful component of the $\chi^{(2)}$ tensor is, in this case, χ_{311} . As a general consideration, the most powerful phase matching method, that is, birefringence phase matching, exploits nondiagonal components of $\chi^{(2)}$, whereas several interesting crystals present very large diagonal components of $\chi^{(2)}$. Such components can be exploited only if the phase-matching conditions are achieved by means of the periodical poling technique.

The commonly used second-order materials are inorganic crystals with oxygen polyhedra, which can be viewed as ionic crystals where one of the ions is replaced by an oxygen polyhedron in an ionized state, stabilized in a noncentrosymmetric configuration by the surrounding ions (usually of metal elements). Examples of such crystals are the ABO_3 type of ferroelectrics, such as LiNbO_3 and KNbO_3 , borates, such as BaB_2O_4 and LiB_3O_5 (usually indicated, respectively, as BBO and LBO), and the isomorphic family with the generic formula MTiOXO_4 , such as potassium titanyl phosphate KTiOPO_4 (usually indicated as KTP).

It is important to note that the requirements for nonlinear materials are not only suitable transparency and high nonlinearity, but also sufficient birefringence for phase-matching, high-optical-damage threshold, good thermal, mechanical, and chemical properties, and possibility of growing large crystals of good optical quality.

Families of crystals possessing a second-order nonlinearity larger than that of inorganic crystals are organic molecular crystals and heteropolar semiconductors. However, at present, they are less interesting for applications because the former has insufficiently good mechanical and chemical properties, whereas the latter is not birefringent. In addition, both families have a limited transparency range.

A possibility that is actively explored is that of starting from an amorphous material (such as a polymer or a silicate glass) and introducing an orientation of noncentrosymmetric molecular groups by heating at a temperature above the glass transition and applying an external field, usually an electric field (electrical poling).

Third-Order Nonlinear Effects

Optical Kerr Effect

If a third-order material illuminated by a monochromatic plane wave at frequency ω propagating along the z -axis is considered, it results from eqn [2] that such a wave gives rise to a nonlinear polarization oscillating at $3\omega_1$. In turn, the nonlinear polarization, once inserted into eqn [1], yields a third-harmonic (TH) optical wave. The entire treatment developed for SH generation, including the phase-matching considerations, can be easily translated to the TH case, and is not repeated here. Instead, the attention is on the polarization term having the expression

$$P(z, \omega) = \varepsilon_0 \left[\chi^{(1)} E(z, \omega) + \chi^{(3)} \alpha |E(z, \omega)|^2 E(z, \omega) \right] \quad [5]$$

where α is a numerical factor that can assume values ranging from $1/2$ to $3/2$, considering different third-order phenomena. From eqn [5], it is possible to define an intensity-dependent susceptibility: $\chi_{\text{eff}}^{(1)} = \chi^{(1)} + \chi^{(3)} \alpha |E(z, \omega)|^2$. By recalling the relation between index of refraction and electric susceptibility and assuming that the nonlinear contribution is small in comparison with the linear one, one obtains

$$n_{\text{eff}} = n + n_2 |E|^2 \quad [6]$$

where $n_2 = \alpha \chi^{(3)} / (2\varepsilon_0 c \chi^{(1)})$. A more careful analysis shows that the overall effect consists in an intensity-dependent deformation of the index ellipsoid of the medium. In particular, an initially isotropic material becomes uniaxial in the presence of a strong linearly polarized optical beam.

Equation [6] expresses the optical Kerr effect. Some phenomena due to such an effect are briefly discussed below.

Optical switch

The phase and the polarization of an optical signal going through a Kerr medium can be changed by illuminating the medium with a strong auxiliary (pump) beam. This opens the way to the realization of all-optical modulators and switches. If the Kerr effect is fast, as it happens when it is due to the displacement of electron clouds, the response time of the device can be as short as the duration of pump pulses (less than 1 ps).

Self-focusing

Considering a pump with a Gaussian transverse intensity profile (this is the output beam from a single-mode laser), the optical Kerr effect produces a transverse index-of-refraction profile that follows the shape of the beam. If n_2 is positive, a greater index of refraction is induced on-axis than in the wings of the beam, creating in this way, a positive lens that tends to focus the beam. This effect is called self-focusing. If the input power is larger than a threshold value, self-focusing can exactly balance diffraction, so that the beam propagates without changing its profile. This phenomenon is called self-trapping. If the input power is further increased, the beam will catastrophically focus, causing in many cases optical damage inside the medium. To conclude this short discussion about self-focusing, it should be mentioned that the effect is very usefully exploited in the so-called Kerr-lens passive mode-locking method for the generation of ultrashort laser pulses.

Self-phase modulation

Considering a beam with a time-dependent intensity profile (optical pulse), the optical Kerr effect gives rise to a self-induced nonlinear phase shift that is also time dependent. Generally speaking, this has the consequence of broadening the frequency spectrum of the optical pulse. It should be recalled that an optical pulse propagating in a linear dispersive medium has a time duration increasing progressively with the propagation distance. Among the various phenomena occurring during the nonlinear propagation of short pulses, it is worth mentioning the existence of optical solitons, that is, pulses of appropriate shape, intensity, and time duration that propagate without changing shape and duration in a medium presenting anomalous group-velocity dispersion. Such a phenomenon is made possible by a compensation between the effects of linear dispersion and self-phase modulation. Particularly important for applications to optical communications is the study of nonlinear propagation in single-mode optical fibers: although the nonlinearity of glass is very small, nonlinear effects can be significant because the intensity can be high and the propagation distance is very large.

Four-Wave-Mixing and Optical Conjugation

The term four-wave-mixing (FWM) refers to the interaction of four waves in a nonlinear medium via the third-order polarization. In the presence of three monochromatic beams at frequencies $\omega_1, \omega_2, \omega_3$, a nonlinear polarization term oscillating at the frequency $\omega_4 = \omega_1 + \omega_2 - \omega_3$, with wave vector $\mathbf{k}_4 = \mathbf{k}_1 + \mathbf{k}_2 - \mathbf{k}_3$, is generated:

Figure 8 Schematic wave-mixing processes: frequency shifter and conjugated mirror.

$$P = \epsilon_0 \chi^{(3)} A_1 A_2 A_3^* \exp[i(\mathbf{k}_1 + \mathbf{k}_2 - \mathbf{k}_3) \cdot \mathbf{r}] \quad [7]$$

Among the various phenomena originated by the nonlinear polarization of eqn [7], two particularly interesting processes are selected (see Figure 8).

Frequency-shifting scheme

In practical situations, a high-intensity beam (pump beam) at frequency $\omega_p = \omega_1$ is sent collinearly with the weak beam (signal beam) 2. The new beam 3 is also collinear, and has a frequency $\omega_3 = 2\omega_1 - \omega_2$. Note that $\omega_3 - \omega_1 = \omega_1 - \omega_2$, that is, ω_3 is the mirror image of ω_2 with respect to the pump frequency. If, for instance, the pump beam is continuous and the signal is a sequence of pulses, the frequency-shifted beam 3 is a temporal replica of the signal beam. It should be added that, in the absence of materials having a large $\chi^{(3)}$, it is usually more convenient to perform the same operation by using a cascade of two second-order processes in a $\chi^{(2)}$ -material. Frequency-shifting devices can be usefully applied in optical communications systems.

Phase-conjugate mirror

If a degenerate case in which all the frequencies coincide is considered, $\omega_1 = \omega_2 = \omega_3 = \omega$, the new field has frequency $\omega_4 = \omega$ and wave vector $\mathbf{k}_4 = -\mathbf{k}_3$, that is, it counterpropagates with respect to beam 3. The nonlinear medium illuminated by beams 1 and 2 acts as a mirror for beam 3: this is what is called a phase-conjugate mirror. Such a mirror has some unique properties compared to an ordinary mirror. First of all, it functions as a retroreflector for any incident angle θ , within the acceptance angle of the experiment. Any phase change $\varphi(\mathbf{r})$ impressed on beam 3 by propagating, for example, through an inhomogeneous medium, will result in exactly the opposite phase $-\varphi(\mathbf{r})$ impressed on the reflected wave, in this way correcting the phase distortion during the back-propagation. In terms of energy balance, the FWM process subtracts one photon from beam 1 and one photon from beam 2, and adds one photon to beam 3 and one photon to beam 4. As a consequence, the reflection coefficient of the conjugated mirror is proportional to the product of the intensities of beams 1 and 2 and can even become larger than 1.

This section concludes with a brief discussion on third-order nonlinear materials. It is useful to distinguish between slow and fast nonlinearities. Slow nonlinearities involve the rotation and alignment of molecular groups under the action of an optical field, such as it may happen in liquid crystals. The effects are large, but the response time can be of the order of milliseconds or even longer. Fast nonlinearities involve the displacement of electron clouds, response times can be in the range of picoseconds but the effects are small. In order to enhance electronic nonlinearities one can operate near a resonance, but the drawback is that response times are now controlled by the material decay time. The most interesting materials are semiconductors or conjugated polymers, but, in practice, the largest fast third-order nonlinearities are obtained by using a cascade of second-order processes in a noncentrosymmetric material.

Stimulated Raman and Brillouin Scattering

Raman scattering is an inelastic light scattering process in which a quantum of excitation is exchanged between the optical field and the scattering medium. A typical case is that of a molecule possessing a vibrational mode with angular frequency ω_v , illuminated by a light beam at frequency ω . The spectrum of scattered light, observed at any scattering angle, will contain, besides the unshifted Rayleigh line at ω , also an additional line, called Stokes line, at frequency $\omega_s = \omega - \omega_v$. The energy difference between the incident and scattered photon is taken to excite the molecular vibration. If the illuminated medium includes molecules that are already in an excited vibrational state, the spectrum of scattered light will contain a third line, called the anti-Stokes line, at frequency $\omega_{as} = \omega + \omega_v$, describing a scattering event in which the molecule has given its vibrational energy to the scattered photon. Raman scattering may

exist also in association with rotational energy levels of molecules. Besides localized molecular excitations, there are also collective excitations producing Raman scattering, such as optical phonons in crystals or plasma waves in an electron gas. It should be noted that not all elementary excitations are Raman active; there are selection rules, usually different from those controlling radiative transitions.

Stimulated Raman scattering (SRS) is observed when two light beams, at frequencies ω and ω_s , are sent into the medium. The Stokes photons generated by SRS are emitted with the same wave vector as that of the incident Stokes field and added coherently to that field. The result is that the field at ω_s is amplified, and, at the same time, more molecules are excited to the vibrational level. SRS can be used not only to amplify a signal at ω_s , but also to generate a coherent wave at ω_s . In fact, if a powerful beam at ω is sent into the medium, it will create Stokes photons by spontaneous Raman scattering, and the created Stokes photons can constitute the seed for an amplification process yielding an intense coherent Stokes field. Note that the spontaneous Stokes photons are emitted isotropically in space, whereas the stimulated Stokes beam will appear in a specific direction satisfying the criterion of maximum overlap between the pump and the Stokes beam. In practice, SRS is observed only in the forward and backward directions.

The growth of the Stokes field along the direction z is described by the equation

$$P_S(z) = P_S(0) \exp \left[\int_0^z g_R P_P(z) dz \right] \quad [8]$$

where g_R (in units of m W^{-1}) is called the Raman gain and $P_P(z)$ is the pump power. SRS is a third-order process; in fact, it can be shown that g_R is proportional to the imaginary part of $\chi^{(3)}$.

If the scattering medium is placed inside an optical cavity, one can build a Raman laser. The Raman laser is different from a normal laser because the pump frequency ω_p can be arbitrary, whereas in normal lasers ω_p must correspond to a transition between the ground level and an excited level of the active medium. As shown in Figure 9, the energy transfer between pump and Stokes can be so efficient that a sequence of Stokes lines of decreasing frequency can be coherently generated. Raman lasers utilizing optical fibers as active medium represent very efficient and powerful sources of coherent radiation: as an example, fiber Raman lasers pumped by a neodymium-laser ($\lambda = 1064 \text{ nm}$) and working on the fifth Stokes line can emit at a wavelength $\sim 1500 \text{ nm}$ with an overall efficiency of 30%.

Any medium at a nonzero temperature presents local fluctuations in the thermodynamic variables that give origin to light scattering. It is assumed that the incident light is characterized by a wave vector $\mathbf{k}$ and an angular frequency ω . In the case of a solid or liquid, the frequency spectrum of scattered light contains an unshifted line (due to nonpropagating density fluctuations) and two lines, called Brillouin lines, centered at frequencies $\omega \pm \omega_B$ that are due to density fluctuations propagating as spontaneous acoustic waves. If the scattering direction is fixed, hence the wave vector of the scattered field, $\mathbf{k}'$, only those spontaneous waves possessing a

Figure 9 Generation of a sequence of Stokes lines in an optical fiber by stimulated Raman scattering. (Reproduced with permission from Cohen *et al.* (1978) *IEEE Journal of Quantum Electronics* QE-14(11): 855–859.)

wave vector $\mathbf{K} = \pm (\mathbf{k}' - \mathbf{k})$ contribute to light scattering in that direction. The frequency shift ω_B of the Brillouin lines corresponds to the frequency of the acoustic phonon which is exchanged in the scattering process. Recalling that the velocity of acoustic waves is given by $u_a = \omega_B/K$, the Brillouin frequency shift can also be seen as a Doppler shift due to diffraction from a traveling phase grating. Although Raman shifts are typically in the range of several terahertz, Brillouin shifts are of the order of some gigahertz.

Stimulated Brillouin scattering (SBS) can occur in a way fully similar to that of SRS. Only the interaction $\mathbf{K} = -(\mathbf{k}' - \mathbf{k})$, corresponding to the situation in which the incident wave reinforces the spontaneous acoustic wave, can give rise to a stimulated effect, generating a coherent wave at the frequency $\omega - \omega_B$. In practice, SBS is observed only in the backward scattering direction. It is interesting to mention that the backward Brillouin wave behaves as the phase conjugate of the pump wave. Therefore SBS can create a phase-conjugate mirror, similar to FWM, but in a simpler way, because only one beam is required.

Introduction

In this article, an overview of the application of linear optical spectroscopies in surface science is given. From a historical point of view, optical methods were important in the very first development of surface-state spectroscopy of clean semiconductor surfaces at the end of the 1960s, when progress in both vacuum technology and surface diagnostics made it possible to reproducibly obtain well-characterized clean surfaces. In fact, optical transitions between filled and empty surface states of intrinsic type were discovered at that time in $\text{Ge}(1\ 1\ 1)2\times 1$ and $\text{Si}(1\ 1\ 1)2\times 1$ by differential reflectance with multiple internal reflections. These results demonstrated the existence of intrinsic (electronic) surface states for the first time in a direct way rather than indirectly from electrical measurements. In the subsequent years, many other surface-sensitive spectroscopies were successfully applied to investigate surface states at the cleavage faces of semiconductors as well as at other clean surfaces.

Generally speaking, in order to study surface optical properties, one has to extract the optical signal originating from the surface from the overwhelming bulk term. For example, in the surface differential reflectivity (SDR), this is accomplished by measuring a change of reflected-light intensity induced by either contamination (usually oxidation or hydrogenation) or chemisorption of foreign atoms. Instead, in reflectance anisotropy spectroscopy (RAS), which is also named reflectance difference spectroscopy (RDS), one measures the reflectance difference for light linearly polarized along two (orthogonal) axes of symmetry at the surface of cubic semiconductors. Since, in general, the surface has a lower symmetry than the bulk, an anisotropy signal originating from the surface is often measured.

When performed with polarized light, SDR yields information on all surface optical transitions (both isotropic and anisotropic) but requires a reference surface, which is obtained by modifying the sample in an irreversible way. On the other hand, RAS does not require any reference surface but is obviously limited to detection of anisotropic transitions only.

The interpretation of the optical experiments is, in general, not straightforward. Hence, the full potentiality of surface optical spectroscopy can be exploited only by a strong interplay of experimental and theoretical work.

At the beginning of the twentieth century, the so-called three-layer model (ambient–surface layer–substrate) was introduced by Drude to describe the surface optical properties from a phenomenological point of view. However, the first steps of the modern theory of surface optical spectroscopy started in 1971, when McIntyre and Aspnes expanded the reflectivity formula for the three-layer model to first order in the surface-layer thickness, obtaining a simple result, suitable for a clear physical interpretation. Realistic and *ab initio* calculations of surface optical properties have later been carried out, even including (in recent years) the electron–hole interaction. At present, the theory is fully developed, but its application to complex surfaces is hampered by the limitations of computational capabilities.

In the following, some relevant results obtained with surface optical spectroscopies, mainly SDR, RAS, and ellipsometry, are briefly described, together with their theoretical interpretations.

Results Obtained with SDR

One of the best-known semiconductor surfaces is the cleavage face of silicon, namely $\text{Si}(1\ 1\ 1)2\times 1$, whose reconstruction is described by the chain model developed in 1981 by Pandey. The optical properties of this surface have been extensively investigated over the years, in particular with reflectance techniques. Figure 1 shows the so-called absorption constant in the near infrared due to transitions between filled and empty surface states possessing a dangling-bond character, at $\text{Si}(1\ 1\ 1)2\times 1$. These pioneering results (1971) were obtained by applying the method of multiple internal reflections to cleaved samples in order to amplify the small surface effect. They proved the semiconducting character of the surface, in spite of the fact that the ideal $(1\ 1\ 1)$ face should be metallic, with an energy gap of ~ 0.45 eV. Similar results were obtained in 1968 for $\text{Ge}(1\ 1\ 1)2\times 1$.

Figure 1 Absorption constant vs. photon energy for Si(1 1 1)2 × 1. (From Chiarotti G, Nannarone S, Pastore R, and Chiaradia P (1971) *Physical Review B* 4; 3398.)

The results of Figure 1 were compatible with Haneman's model, in which the lack of equivalency of surface atoms was explained by a charge transfer associated with a partial dehybridization, due to their up and down displacement with respect to the surface plane. These results were indeed interpreted in the framework of that model. However, when the chain model appeared many years later, its pronounced one-dimensional character suggested a strong anisotropy of the optical properties, at variance with what was predicted by Haneman's model. Indeed, this prediction was confirmed by another experiment with linearly polarized light. Figure 2 shows the surface reflectance peak (analogous to the absorption peak of Figure 1) for light polarized parallel and perpendicular to the chains of surface atoms at single domain Si(1 1 1)2 × 1. The results, recently confirmed by RAS, point out that this peak is totally anisotropic, thus providing a convincing evidence for the chain model.

In 1999, Rohlfing and Louie carried out a calculation of the optical properties of this surface, according to the method of the Bethe–Salpeter equation to account for the electron–hole interaction. The result (see Figure 3) has suggested that the experimental peak in Figure 2 is due to a bound exciton, with the electron and hole in two surface-state bands with a binding energy of 0.27 eV.

Results Obtained with RAS

RAS was developed as a modulation technique distinct from SDR (in USA) by Aspnes and in Russia by Safarov, independently, in the mid-1980s.

In the beginning, Aspnes mainly studied optical anisotropies of real surfaces of elemental semiconductors, in particular, Si substrates for technological applications. These anisotropies, ~1%, are not related to intrinsic surface states. They are, instead, associated to a lower symmetry of the subsurface region with respect to the (cubic) bulk, which perturbs the bulk-state wave functions, a situation often described as “bulk states modified by the surface.” Figure 4 shows an example of these surprising anisotropies in the case of oxidized Si(1 1 0).

It is seen in Figure 4 that the line shape of the surface anisotropy clearly mimics the imaginary part of the bulk dielectric function of Si. While oxidized Si(1 1 0) now has become a standard for calibration of RAS apparatuses, the interpretation of spectra, such as those of Figure 4, is still an intriguing matter. After some controversies on the origin of the spectrum in Figure 4, the last calculations carried out, including the electron–hole interaction by Bechstedt and co-workers, have finally shown that it can be explained in terms of surface effects on the bulk resonant exciton underlying the E1 peak, close to 3.4 eV.

Since optical techniques can be performed in metal organic chemical vapor deposition (MOCVD) environments as well in vacuum, RA spectra during growths of GaAs(0 0 1) by both molecular beam epitaxy and MOCVD have been compared. As a result, a striking correspondence has been found between RAS signals characteristic of surface reconstructions in vacuum and those obtained in an MOCVD reactor at atmospheric pressure of hydrogen in suitable conditions. Figure 5 shows this correspondence, demonstrating that local ordering is the same in the two cases.

Figure 2 Differential reflectivity spectra of a single domain $\text{Si}(1\ 1\ 1)2\times 1$ surface, for light polarized along the $[-211]=x$ and $[0\bar{1}1]=y$ directions. The LEED pattern is sketched in the inset. (From Chiaradia P, Cricenti A, Selci S, and Chiarotti G (1984) *Physical Review Letters* 52: 1145.)

(Reproduced with permission from Rohling M and Louie S G (1999) *Physical Review Letters* 83: 856.)

Calculations have been carried out for various reconstructions of $\text{GaAs}(00\ 1)$, using both semi-empirical and *ab initio* methods, in order to understand the origin of the observed structures. A good explanation of the RAS of the As-rich reconstructions has been obtained. Most of the RAS structures arise from transitions across surface-perturbed bulk states. However, on the (2×4) reconstruction, a combined energy loss and RAS experimental work have recently revealed true surface-state transitions at ~ 2.5 eV, well below the first bulk critical point. The optical properties of the Ga-rich $(00\ 1)$ surface, instead, are not yet completely understood. In recent years, interesting RAS investigations have been performed on other semiconductor surfaces, both clean and covered with

monolayers of alkali atoms, by the groups of Richter and Paget. Also, organic molecules deposited on different substrates have been studied by RAS, especially by Weightman and Chiaradia-Goletti. Moreover, RAS shows promise to yield valuable information on low-dimensional systems (quantum wires and dots) and nanostructures (carbon nanotubes, polymers, etc.).

Results Obtained with Ellipsometry

Ellipsometry measures changes in the polarization parameters of light upon reflection from a surface. These parameters are: the relative phase Δ and the relative amplitude ratio $\arctan \Psi$ of the two components of linearly polarized light, parallel and perpendicular to the plane of incidence,

$$r^p/r^s = \tan \Psi \exp(i\Delta) \quad [1]$$

From the spectral dependence of Δ and Ψ , the optical constants n and k are obtained by making use of the Fresnel formulas for the reflection coefficients r^p and r^s .

When surface properties are studied by ellipsometry, a differential method has to be used, as in the case of SDR. Thus, the changes $\delta\Delta$ and $\delta\Psi$ of the ellipsometric parameters are recorded upon adsorption of a gas. Under simplifying hypotheses, in the framework of the usual three-layer model, the optical constants of the surface are eventually obtained.

Starting from the pioneering work of Mayer in the 1970s, ellipsometry has been applied to derive the surface optical constants of a number of clean semiconductor surfaces. Especially, various crystallographic faces of Si and Ge, as well as the cleavage faces of GaP, GaAs, and ZnO, and also a number of metallic surfaces have been investigated by this technique.

In spite of the seemingly greater complexity in the data reduction, the results obtained by ellipsometry are practically coincident with those obtained by reflection-based methods, as demonstrated, for instance by the spectra of Figure 6, reporting the dielectric anisotropy obtained from both RAS and ellipsometry data for GaAs(001) 2×4 .

Other Experimental Techniques

Many other optical techniques have contributed in the past to the development of surface physics. Although some of them have fallen into disuse, they deserve to be mentioned here: surface photoconductivity, surface photovoltage, photothermal displacement spectroscopy, and surface photoluminescence. A review of the main results obtained by means of these techniques, especially in the field of clean semiconductor surfaces, can be found in the literature.

Theory

Theoretical work is needed in order to fully exploit the potentiality of surface optical spectroscopy. Three steps are involved in the theory: (1) the determination of one-electron wave functions; (2) the calculation of the dielectric susceptibility, possibly including many-body interactions; and (3) the solution of light-propagation equations. The last problem was solved in a quite simple way at the end of the 1970s. The surface contribution to reflectivity (i.e., the reflectance difference with and without the surface layer) can be calculated according to the formula:

$$\Delta R/R = 4 \left(\frac{\omega}{c} \right) \cos \theta \operatorname{Im} \left\{ \frac{\Delta \epsilon_{yy}}{(\epsilon_b - 1)} \right\} \quad [2]$$

for s-light incident from vacuum in the xz -plane and polarized in the y direction.

Figure 6 Dielectric anisotropy of GaAs(100) 2×4 , as obtained from reflectance difference spectroscopy (RDS) and from surface differential ellipsometry (SDE). (Reproduced with permission from Wassermeier M, Behrend J, Ploog KH, Zettler JT, Stahrenberg K, and Richter W (1996) *Physical Review B* 53: 13542.)

Here, θ is the angle of incidence, and

$$\Delta\epsilon_{\gamma\gamma} = \int_{-\infty}^{\infty} dz \int_{-\infty}^{\infty} dz' [\epsilon_{\gamma\gamma}(z, z') - \delta(z, z')\epsilon_0(z)] \quad [3]$$

$\epsilon_0(z) = \theta(-z) + \epsilon_b\theta(z)$ is the zeroth-order dielectric constant yielding Fresnel formulas, and $\epsilon_{\gamma\gamma}(z, z')$ is the relevant component of the nonlocal dielectric tensor of the solid–vacuum interface.

For a microscopic evaluation of surface optical properties, one has to calculate eqn [3]. If excitonic and local-field effects are neglected, $\epsilon_{\gamma\gamma}(z, z')$ can be computed from one-electron wave functions. It is usually evaluated mimicking the semi-infinite crystal by a slab of several (from 10 to 30) atomic layers. In this case, the right-hand side of eqn [3] is related to the slab dielectric function. Within the single-particle scheme, its imaginary part is simply related to the transition probability induced by the radiation between slab states:

$$\epsilon_{\gamma\gamma}^{(2)}(\omega) = (8\pi^2 e^2 / m^2 \omega^2 A) \sum_k \sum_{v,c} |p_{vc}^{\gamma}(k)|^2 \times \delta(E_c(k) - E_v(k) - \hbar\omega) \quad [4]$$

where $p_{vc}^{\gamma}(k)$ is the matrix element of the γ -component of the momentum operator between initial (v) and final (c) slab states at the point k in the two-dimensional Brillouin zone (BZ), and A is the sample area. The real part is computed via the Kramers–Kronig relation.

One more ingredient entering eqn [2] is the bulk dielectric function, whose imaginary part is analogous to eqn [4], where, now, eigenstates and eigenvalues of the infinite crystal, together with three-dimensional k vectors, are involved. The study of the optical response of surfaces within the single-particle picture amounts then to calculating (1) the single-particle spectrum and (2) the transition probability between occupied and unoccupied states, both for the perfect crystal and for the crystal with a surface.

If the dielectric susceptibility $\epsilon_{\gamma\gamma}(z, z')$ is assumed to be local, and a three-step model is hypothesized for its z dependence, the formula of McIntyre and Aspnes mentioned in the section “Introduction” is recovered.

The one-electron states appearing in eqn [4] should be obtained, strictly speaking, within the theory of Green’s functions, by solving the quasiparticle Schrödinger-like equation. In this framework, electrons move in a potential which is the sum of the ion potential, the Hartree potential due to the electronic charge density, and of a nonlocal energy-dependent self-energy, which accounts for exchange-correlation (XC) effects due to the interaction with the other electrons. The so-called GW approximation to the self-energy, developed by Hedin in 1965, completes the recipe for a rigorous calculation of band energies in solids. Calculations carried out starting in the 1980s have yielded band energies in agreement within 0.1 eV with experimental values for semiconductors.

GW calculations of the electronic structure of solids are computationally very demanding. Hence, as in the past, before the advent of vector computers, even now for complex systems, simpler – yet less accurate – methods are being used. Semi-empirical methods include the tight-binding and pseudopotential methods, where the matrix elements of the Hamiltonian (in the former case) or of the total potential (in the latter case) between basis functions (local orbitals in the former case, plane waves in the latter) are fitted to reproduce bandgaps at some high-symmetry points of the BZ, obtained from experiments. An *ab initio* method often used to determine the band structure of solids is the density-functional theory (DFT), where the XC self-energy is substituted by a local energy-independent XC potential, which is a functional of the electron density. Optical spectra calculated for bulk semiconductors within the one-electron approximation yield only qualitative agreement with experimental spectra, no matter which method – semi-empirical or *ab initio*, GW, or DFT – is used. This is because the excitonic and local-field effects are neglected. When these are considered, the discrepancies disappear, as it was shown first by Hanke and Sham in 1980 with a tight-binding calculation. *Ab initio* calculations of the optical properties of bulk solids including the electron–hole interaction and local-field effects yield quantitative agreement with experiments.

The most used methods to calculate surface optical properties are those relying on the single-particle approximation, ranging from the simplest (less accurate) ones (such as semi-empirical tight binding) to the rigorous quasiparticle GW method. Anyway, if the electron–hole interaction is not included, one can expect only a qualitative description of the spectra. The inclusion of the electron–hole interaction in the calculation of excited spectra leads one to consider a two-particle problem (the Bethe–Salpeter equation) rather than a single-particle problem (the Schrödinger-like equation for quasiparticles). Hence, the computational cost increases dramatically and makes the method usable, at present, only for simple surfaces.

The semi-empirical tight-binding method, for its computational speed, has been the first method used for calculating surface optical properties in 1986, when it was successfully applied to Si(1 1 1) 2×1 and explained the strong optical anisotropy shown in Figure 1. In spite of its limitations, this method has yielded, in many cases, results in qualitative agreement with experiments and has helped in clarifying the atomic and electronic structure of a number of surfaces.

Ab initio methods have been developed in the last decade within DFT local-density approximation (DFT-LDA), by expanding the wave functions in plane waves and using nonlocal norm-conserving pseudopotentials. Finally, a rigorous one-electron calculation of surface optical properties should rely on the Green’s function approach, with the electron self-energy calculated according to the GW approximation. These approaches are much more demanding than semi-empirical tight binding from the computational point of view, since a great number of plane waves are needed to represent slab wave functions.

As an example, the case of GaAs(1 1 0) is discussed. First-principles calculations including self-energy corrections according to the GW approximation have been carried out for this surface and are shown in Figure 7. They are compared to room temperature (RT) experiments carried out by Esser and co-workers. Calculations show that the experimental peak at 2.7 eV has a substantial

Figure 7 Reflectance anisotropy of GaAs(1 1 0). Upper curve: DFT-LDA calculation. Middle curve: *GW* calculation. Lower curve: RT experiment. (After Del Sole R, Palummo M, and Pulci O (2004) In: Cricenti A (ed.) *Epioptics-7*, p. 1. World Scientific.)

(~50%) contribution arising from transitions across surface states, while all other structures are due to transitions across surface-perturbed bulk states. The reflectance anisotropy calculated in this way has the main structures in very good agreement with experimental ones as far as energy positions are concerned, while the DFT-LDA calculation, also shown in Figure 7, is considerably red-shifted, as a consequence of the DFT “gap problem.” Differences in line shapes are still present, which are expected to be fixed by introducing excitonic and local-field effects in the calculations.

Finally, the inclusion of the electron–hole interaction can be performed by solving the Bethe–Salpeter equation at surfaces. The first calculation of this kind, carried out by Rohlfing and Louie for Si(1 1 1)2×1 in 1999, is shown in Figure 3. As it was mentioned before, the SDR peak at 0.45 eV is ascribed to a surface-state bound exciton, which takes over most of the oscillator strength of the transitions across the dangling-bond (DB)-like surface states. As a consequence, these transitions become very weak and are hardly visible in the experimental spectra. Another application of this technique has been done by Bechstedt and co-workers in 2002 for Si(1 0 0):H, which explained the line shape of the RAS spectrum of Figure 4 as due to a polarization-dependent quenching of bulk excitonic effects close to 3.4 eV.

Conclusion

Optical spectroscopy has become, in the last decades, an important tool for surface analysis, of great sensitivity to structural changes and versatility. The theoretical understanding of the results is becoming more and more satisfactory, thanks to the application of advanced many-body techniques to the simulation of surface optical properties. Nevertheless, some problems are still open: the most obvious is the extension of these techniques to complex surfaces (those with higher-order reconstructions), which is hampered by the current computational limitations. Less obvious problems are those related to the electron–phonon interaction, which affects surface optical line shapes in a drastic way, and to the complex morphological structure of surfaces, arising from steps, multiple domains, and defects, whose study is now at an initial stage.

Introduction

A major use of X-rays, ever since they were discovered over a century ago, has been and still is the visualization of the inside of systems, opaque for other probes. Whatever the imaging process used, it implies an inhomogeneous response of the sample to the beam. Recently, X-ray imaging techniques have dramatically progressed, in connection with the improvements in sources (synchrotron radiation), detectors, and computer image processing. Among these new features, three-dimensional imaging with spatial resolution in the micrometer range (microtomography), the sensitivity enhancement associated with phase contrast imaging, and new X-ray microbeam-based imaging approaches such as fluorescence or diffraction microtomography are discussed below.

This section is devoted to another way of obtaining X-ray images, based on Bragg diffraction: the ‘X-ray topographic’ techniques (the ‘historical’ name is retained: it is widely used, but misleading because it suggests that these techniques are surface techniques, whereas very often they are used to probe the bulk of single-crystal samples). They were mostly developed in the late 1950s and 1960s to visualize defects and distortions in crystals. Work performed on silicon made the routine production of large perfect crystals, as used by the microelectronics industry, possible. These techniques are nondestructive and sensitive to a large range of distortions (typically in the 10^{-3} – 10^{-8} range). Understanding the main contrast mechanisms implies knowing how crystal imperfections modify the diffraction behavior of the underlying perfect crystal. The dynamical theory of diffraction describes this behavior. The specific contributions of synchrotron radiation (and, briefly, neutrons) are outlined.

Figure 1 Principle of the topographic methods.

Principle of the Topographic Techniques

X-ray topography is an imaging technique for single crystals based on Bragg diffraction. The local variations of the amplitude or direction of the diffracted beam provide information on crystal inhomogeneities such as defects, domains, or phases. This information is often averaged out, and lost, when using usual diffraction methods.

Figure 1 schematically represents the main idea of all the diffraction imaging methods. The single-crystal sample *C* is set to diffract a fraction of the incoming beam, according to Bragg's law, $2d \sin \theta_B = \lambda_h$. The diffracted beam is recorded on a position-sensitive detector (usually X-ray films, nuclear plates or, increasingly, CCD cameras equipped with a high-resolution scintillator). If a small volume *V* within *C* behaves differently from the matrix, intensity variations ('contrast') can be produced on an area *S* of the two-dimensional image produced by the diffracted beam. This contrast only occurs if the platelet-shaped crystal displays inhomogeneities.

The inhomogeneities that can be visualized using X-ray diffraction topography include defects such as dislocations (**Figure 2**), twins, domain walls, inclusions, impurity distribution, and macroscopic deformations, such as bending or acoustic waves, present within the single-crystal sample.

Figure 3 is an example of such a topographic image. It shows the image recorded using the 444 reflection from a flux-grown platelet-shaped gallium-substituted yttrium iron garnet crystal ($\text{Y}_3\text{Ga}_x\text{Fe}_{5-x}\text{O}_{12}$, with $x \sim 1$, Ga – YIG) using the $\text{MoK}\alpha_1$ radiation from a standard X-ray generator.

In addition to a distorted region on the upper corner, associated with the crystal fixation, various features are observable on this topograph: dislocations, growth striations and growth sectors, magnetic domains, dissolution bands, and the initial stage of a crack.

Figure 2 Schematic drawing of a dislocation, characterized by its line direction (the border of the incomplete atomic plane in this case) and the Burgers vector *b* (in this case – 'edge' dislocation – horizontal and perpendicular to the line direction).

Figure 3 Topograph of a flux-grown Ga-YIG crystal.

These features are observed because they entail a distortion of the crystalline lattice. It is worth giving the typical value of these distortions, which include either a lattice rotation $\delta\theta$, or a lattice parameter variation $\Delta d/d$, or a combination of both. For the growth striations, which are the main observable features, this distortion is in the 10^{-4} range, whereas the variation of magnetostriction associated with the magnetic domains, as well as the distortion between growth sectors, are in the 10^{-6} range. The distortion associated with dislocations is a function of the distance to the core; at the level of the image border, it is in the 10^{-5} range. Large contrast on the image can, therefore, correspond to rather weak distortions, showing that these techniques are very sensitive.

Some Results of Dynamical Theory

A few results of the dynamical theory, necessary to understand the contrast mechanisms, are given below. The discussion is restricted to symmetrical transmission geometry as shown in **Figure 1**.

In the case of a monochromatic plane wave beam, and a perfect crystal set in Bragg diffraction position (**Figure 1**), two 'wavefields' propagate within the crystal if the direction of the incident beam propagation vector lies within an angle ω_h around the exact Bragg position (ω_h the intrinsic width of the diffraction curve, often called the Darwin width, being of the order of $10^{-5} - 10^{-6}$ rad:

$$\omega_h = (2\lambda^2 C_p |F_h| r_0) / (\pi V_c \sin 2\theta_B) \quad [1]$$

where C_p is the polarization factor ($C_\pi = \cos 2\theta_B$ for π polarization, i.e., for the electric field vector E in the scattering plane, and $C_\sigma = 1$ for σ polarization, i.e., for E perpendicular to this plane), r_0 is the 'classical electron radius' (2.8×10^{-15} m), V_c is the unit cell volume, and F_h is the structure factor corresponding to the Bragg reflection used. A wavefield corresponds to the superposition of one diffracted and one forward-diffracted wave, coupled because the perfect crystal is set for Bragg diffraction. These waves decouple outside the crystal, producing two beams, parallel to the incident and diffracted directions, respectively (**Figure 4**).

In the case of a monochromatic spherical wave, wavefields propagate and interfere within the whole 'Borrmann' fan or Borrmann triangle ABC (**Figure 4**). The characteristic coupling length between wavefields is $\mathbb{L}_0$ (extinction length, or Pendellösung period), which corresponds, in the case considered, to the distance necessary for most of the energy participating in the diffraction process to move from the transmitted to the diffracted direction, or vice versa:

Figure 4 Propagation of wavefields within the 'Borrmann' triangle ABC in the case of a perfect crystal.

Figure 5 Reflecting power ρ of a nonabsorbing perfect crystal as a function of the reduced thickness t/Λ_0 for the transmission ('Laue') and reflection ('Bragg') cases. The kinematical approximation limit is also shown.

$$\Lambda_0 = (\pi V_c \cos \theta_B) / (\lambda C_p |F_h| r_0) \quad [2]$$

Typical values of Λ_0 are in the 1 – 100 μm range.

If the crystal is rotated in a monochromatic beam, or if the beam is polychromatic, the diffracted power is a function of this 'variable' (angle, or wavelength), leading to the integrated reflectivity ρ , defined as the area under the diffraction curve. **Figure 5** shows ρ for a nonabsorbing perfect crystal, as a function of t/Λ_0 , t being the thickness of the platelet-shaped crystal, for both the transmission ('Laue') and reflection ('Bragg') cases. These curves show that

- ρ is proportional to t for $t \ll \Lambda_0$ ('kinematical' limit of the dynamical theory);
- ρ is nearly constant for $t \gg \Lambda_0$, the saturation value being proportional to $|F_h|$; and
- ρ displays an oscillatory behavior in the Laue case (the image produced by a low-absorption wedge-shaped crystal will, therefore, exhibit 'equal thickness' fringes associated with the maxima and minima of the curve, and to the varying thickness of the crystal). Its saturation value, for $t \gg \Lambda_0$, is half of the one corresponding to the Bragg case.

Effect of Imperfections: Contrast Mechanisms

For a nonabsorbing plate-shaped crystal illuminated by a parallel and polychromatic beam (a good approximation for the simplest and presently the most usual topographic technique, white beam synchrotron radiation topography), within a very simplified approach, the direction and intensity of the locally diffracted intensity depends upon

- the structure factor F_h ;
- the angle θ formed by the considered lattice planes, and the incident beam; and
- Y , a parameter that incorporates the modifications introduced by the crystal inhomogeneities on the perfect-crystal dynamical theory results.

The beams diffracted by two neighboring regions I and II of the sample produce contrast on the topograph if

- $(F_h)_I \neq (F_h)_{II}$, where the differences can either reside in the modulus or the phase or the structure factor. This structure factor contrast is the main contrast mechanism in neutron diffraction topography of magnetic domains, the magnetic structure factor often being different for the various domains (**Figure 6**);
- $\theta_I \neq \theta_{II}$, that is, regions I and II are misoriented – subgrains, domains, etc. – one with respect to the other: this is orientation contrast; **Figure 7** shows, for instance, white or black thick lines, corresponding to the separation, or superposition, of the images of subgrains;
- $Y_I \neq Y_{II}$, the two regions display extinction contrast.

Imperfections modify the perfect-crystal behavior described by the dynamical theory. They can hide the interference fringes, or lead to locally enhanced or reduced diffracted intensity, depending on the absorption conditions. New images can occur through the decoupling of a wavefield and the creation of new wavefields at a defect.

In the low-absorption case, the predominant contrast mechanism is the so-called direct-image process. Assume again (**Figure 1**) that a polychromatic, extended beam impinges on a crystal such that a small crystal volume V contains a defect (inclusion, dislocation, etc.) associated with a distortion field, which decreases with growing distance from the defect core. A wavelength range $\Delta\lambda/\lambda = \omega_h/(\tan\theta_B)(\sim 10^{-4})$ participates in diffraction by the 'perfect' matrix crystal, whereas regions around the defect are at the Bragg

Figure 6 The observation, by neutron diffraction topography of antiferromagnetic domains in NiO is an example of 'structure factor contrast.' These domains are characterized by their propagation vector, which lies along one of the four equivalent $1\ 1\ 1$ directions; each type of domain has a nonzero magnetic structure factor for the Bragg reflection corresponding to its propagation vector, and zero for the other three magnetic reflections: (a) $1, 1, -1$, (b) $-1, 1, 1$, (c) $-1, 1, -1$, and (d) drawing of the domain configuration – type I is missing in the investigated crystal. These images were recorded – exposure times ~ 10 h – using a ^{157}Gd screen acting as $n - \beta$ converter and X-ray film; 'white' means more illuminated.

Figure 7 White beam topograph of an Fe – 3%Si crystal, $E \approx 25$ keV, showing orientation contrast associated with subgrains. A fir-tree magnetic domain pattern is also visible.

position for components of the incoming beam which are outside this spectral range. The defect thus leads to additional diffracted intensity on the detector.

The regions that produce the direct image of a given defect are some distance away from the core of the defect. This distance depends not only on the nature of the defect, but also on the diffraction process itself. The lattice distortion acts on diffraction through an angle, the effective misorientation $\delta\theta$, which reflects the change in the departure from the Bragg angle that is associated with the existence of the defect:

$$\delta\theta(\mathbf{r}) = -(\lambda/\sin 2\theta_B)\partial(\mathbf{h} \times \mathbf{u}(\mathbf{r}))/\partial(s_h) \quad [3]$$

where $\mathbf{h}$ is the undistorted reciprocal lattice vector, $\mathbf{u}(\mathbf{r})$ is the displacement vector, and $\partial/\partial(s_h)$ is the differentiation along the reflected beam direction. It was shown that the width of the direct image corresponds to the contribution of regions such that $\delta\theta$ is of the order of ω_h . This can be understood when considering that the regions where the distortion is $<\omega_h$ are within the diffraction range of the perfect crystal, and that those where the distortion is $\gg\omega_h$ have a negligible contribution for the considered Bragg diffraction spot. This leads to 'intrinsic' image widths, for an edge dislocation such as the one schematized in Figure 2, $\sim\Lambda_0|\mathbf{b} \cdot \mathbf{h}|/4$ ranging in the 1–100 μm scale, and therefore implies a limitation on the density of defects that can be resolved on a topograph ($\sim 10^4 - 10^5 \text{ cm}^{-2}$ for dislocations).

This also implies that direct images are only seen in crystals that are thick enough. Indeed, the dynamical theory predicts a width ω_h for thin ($t < \Lambda_0/\pi$) crystals inversely proportional to the thickness. If the crystal is thin, only very distorted regions with a strongly reduced volume – and consequently reduced diffracted intensity – can contribute to the direct image, which cannot therefore be observable.

The effective misorientation $\delta\theta$ allows, in addition, determining on which reflections a given defect can produce an image. Equation [3] shows that $\delta\theta = 0$ if $\mathbf{u}$ is perpendicular to $\mathbf{h}$. The defect is not visible on the corresponding topographs. A dislocation, for instance, is usually not visible when $\mathbf{h} \cdot \mathbf{b} = 0$, $\mathbf{b}$ being the Burgers vector. The invisibility criteria are powerful ways of characterizing the defects.

The effective misorientation can also be written as a function of the local variation in the rotation $\delta\phi$ of the concerned lattice planes and the local relative variation in the lattice parameter, $\Delta d/d$, as

$$\delta\theta = -(\Delta d/d) \tan \theta_B \pm \delta\varphi \quad [4]$$

when taking absorption into account, the situation can change drastically. Direct images do not occur in the high-absorption case ($\mu t > 10$), and are replaced by dips in the intensity corresponding to the disruption of a dynamical-theory-related effect, the anomalous transmission (also called the Borrmann effect). Both types of images ('additional' intensity and 'dips') are simultaneously present on the topographs, as well as interference fringes ('dynamical' and 'intermediary' images) for samples with intermediate absorption ($\mu t \sim 2-5$).

Diffraction Topographic Techniques

As already discussed, Bragg diffraction imaging may be used either in transmission or in reflection. In addition, the beam can be extended or restricted, and the image can be an integrated or a nonintegrated one.

Figure 1 shows an extended, divergent, and/or nonmonochromatic beam illuminating the whole sample, or a large area. This results in an image which can, to a first approximation corresponding to the predominance of the direct images, be considered as the projection of the defect distribution along the diffracted beam direction. The incident beam can also be restricted to a small width (typically 10–20 μm) in the scattering plane. In the same first approximation, this produces an image of those defects intercepted by the blade-shaped incident beam, hence the name 'section' topograph.

A better definition of the extended/restricted beam distinction is based on the width of the Borrmann triangle, $w_B = 2t \sin \theta_B$ in the symmetrical Laue case, t being the crystal thickness. The extended beam, or projection topograph, situation corresponds to the case where the width w of the incoming beam in the scattering plane is such that $w \gg w_B$. The restricted beam, or section topograph, case corresponds to $w < w_B$.

In the section topography, the position of the direct images within the image can be used to extract the depth of the related defects in the crystal, one edge of the image corresponding to the entrance face of the sample, the other to the exit surface. In very good crystals, with small or moderate absorption, the same interference effect that leads to the oscillations shown in Figure 5, produces interference fringes, called Kato's fringes. These fringes are very sensitive to crystal distortion, and their modification is one of the first indications of a departure from the perfect-crystal situation (see Figure 11).

The use of a polychromatic beam with a sufficiently wide bandwidth often offers advantages. Several reflections are recorded simultaneously, which is very helpful when characterizing defects or phenomena, and misoriented regions within a sample diffract at once, each region finding a wavelength λ that satisfies the local Bragg condition. This 'white beam' version of diffraction topography is identical to the well-known Laue technique, except that the incident beam is broad. Each Bragg spot is now a topograph. This is an integrated wave diffraction image, because it results from the superposition of contributions from a range of wavelengths. It is mainly sensitive to the variations of lattice plane orientation $\delta\phi$, which produce a change in the diffracted beam direction, and not to $\Delta d/d$. 'White beam' topography is widely used at synchrotron radiation facilities. The exposure time is often of the order of a fraction of a second, and it is possible to follow the evolution of any one of the Bragg spots in 'real time,' using a CCD camera equipped with a scintillator.

White-beam X-ray topography (WBXRT) have been used to study formation micro-cracks and associated strain fields produced by nano-indentations in Si wafers (Allen *et al.* 2010). Oriwol *et al.* (2013) revealed dislocation pile-ups and formation of smallangle subgrain boundaries with spacing between dislocations up to 28 nm in block-cast multicrystalline silicon using WBXRT.

Figure 8 Bragg case plane wave topographs of a quartz plate with nonhomogeneous distributions of impurity atoms in different growth sectors and in the seed plate (rectangle in the middle part), $40\bar{4}0$ reflection, $E=8.04778$ keV, k_0^p is the projection of the wave vector of the incident wave on the crystal surface; the topographs were recorded at $\sim 40\%$ of the maximum intensity on the low-angle side (left image) and $\sim 20\%$ of the maximum intensity on the high-angle side (right image) of the rocking curve.

The incident beam on the sample can also be monochromatized. This ‘monochromatic wave’ nevertheless displays a range of wavelengths ($\Delta\lambda/\lambda$) as well as an angular divergence ω . Let ω_c be the diffraction width of the crystal (which reduces to ω_h in the case of a ‘perfect’ crystal). If the divergence ω (and/or $(\Delta\lambda/\lambda) \tan \theta_B$) $> \omega_c$, the image is still an integrated wave topograph.

If ω (and $(\Delta\lambda/\lambda) \tan \theta_B \ll \omega_h$), the technique is called plane wave topography. It is not only suited to detect weak deformations ($10^{-6} - 10^{-8}$ range), but also to obtain images of defects such as dislocations (see **Figure 9**) with much more details than in the case of direct images. Its use allows a quantitative analysis, because the local diffracted intensity is closely related to the effective misorientation. An example of the use of ‘plane wave’ topography is shown in **Figure 8**: the seed of the investigated quartz crystal and the various growth sectors exhibit different impurity contents, which result in small variations of the lattice parameter (in the $10^{-5} - 10^{-7}$ range).

If an image is recorded at an angular position very far away (typically a few ω_c) from the center of the diffraction curve, the main contribution to Bragg diffraction originates from the distorted regions, and not from the perfect-crystal matrix. This allows reducing the ‘intrinsic’ width of the images and is known, by analogy with electron microscopy, as weak beam topography (**Figure 9**).

Synchrotron Radiation Topography: Real-Time Investigations and Coherence-Related Effects

Synchrotron radiation is now widely used for X-ray imaging. The typical exposure time to record a synchrotron radiation topograph is a fraction of a second. It is therefore possible to investigate evolving phenomena such as the movements of defects, boundaries during first-order phase transitions, or domains. Specific sample environments (cryostat, furnace, electric or magnetic field, strain, etc.) are added for each particular experiment. Image subtraction can help emphasize changes with respect to a reference state.

In recent studies, synchrotron radiation X-ray topography has been an effective technique for characterizing crystal quality, dislocations and imperfections in crystalline thin films. The topographies revealed crystalline imperfections in strained Si layer where several centimeters in size macule pattern and crosshatch patterns were observed on supercritical-thickness strained

Figure 9 111 topographs of a Ge crystal recorded using the beam (35 keV) produced by an Si 111 monochromator: (a) top of the rocking curve, and (b) on the high-angle tail of the rocking curve (‘weak beam’ image).

Figure 10 Stroboscopic topograph showing the propagation of surface acoustic waves – $12\ \mu\text{m}$ wavelength – in a LiNbO_3 crystal. Wave front distortions caused by the interaction of the waves with dislocations are visible. One dislocation region is framed. (Courtesy of E. Zolotoyabko.)

silicon-on-insulator (SC-sSOI) wafers (Shimura *et al.* 2012). In Jussila *et al.* (2013) works, synchrotron radiation topographs indicated misfit dislocations which lead to critical thickness and crystal quality of $\text{GaP}_{0.98}\text{N}_{0.02}$ layers grown on GaP substrates evaluation. Furthermore, the technique was also used to trace changes in density of microdefects and dislocation structure of grown ZnGeP_2 crystals (Verozubova *et al.*, 2014).

It is possible to investigate quicker phenomena if they are periodic, through stroboscopic imaging. Choppers located on the beam path and synchronized with periodic magnetic or electric fields were used to investigate phenomena such as the motion of magnetic domains or the evolution of conduction channels, in the 10^{-2} – 10^{-3} s range. Stroboscopic experiments on bulk or surface acoustic waves, in the 10^{-8} – 10^{-9} s range, were performed using the pulsed structure of the synchrotron radiation source itself (Figure 10).

The small source sizes and the large source-to-sample distances, which are now common features of modern synchrotron radiation facilities, lead to highly coherent X-ray beams, which can be used for diffraction topography. In this case surface inhomogeneities, or porosities, can be imaged in the diffracted beam even when they do not produce a strain field through their Fresnel diffraction image. Recording images at various sample-to-detector distances allow retrieving the phase jump involved in these images. The use of Bragg diffraction imaging with a coherent beam can even, in special cases, produce structural information at the atomic level, even though the spatial resolution of the images is on a much larger scale of micrometers. For instance, diffraction topographs of ferroelectric crystals, using a coherent beam, give access to a very elusive microstructural piece of information: how ferroelectric domains are connected across the domain wall and, in particular, how they match at the atomic level.

Simulations of X-Ray Topographs

The information provided by the topographs allows a detailed quantitative analysis. This is performed through simulations. The simulation process requires introducing a deformation field with free parameters that will be refined by comparing the simulated image to the experimental one. Depending on how rapidly the distortions (expressed by the effective misorientation $\delta\theta(r)$) change locally within the crystal, this may be done using diffraction theories with various complexities. In the case of Figure 8, the Bragg case plane wave topographs of a quartz plate with nonhomogeneous distributions of impurity atoms, the local application of the dynamical theory for perfect crystals already provides very good results. In this case, the diffracted intensity can be approximated by the simple formula $I_h = I_M R_N(\theta_A - \delta\theta)$, where R_N is the rocking curve of the setup, I_M is a normalization factor, and θ_A is the Bragg angle in a crystal part assumed as the perfect reference one. This means that the contrast depends on the position of the ‘working point,’ which is determined, through the parameter $\delta\theta(r)$, by the local Bragg angle on the perfect reference-rocking curve. For faster varying deformations (Figure 11), a geometric-optical approximation may be chosen. The most general case requires a wave-optical approach, which is necessary to calculate, for instance, the contrast of a dislocation. The algorithms give very good results for the plane wave case.

Figure 11 Measured (left) and calculated (right) 422 section topographs of a 565 μm thick silicon crystal with the edge of a 150 nm silicon oxide film, $E = 17.48$ keV.

Conclusion

X-ray diffraction topography is an invaluable tool to characterize single crystals and investigate many-crystal physics phenomena (creation of defects, domains, phase transitions, vibrations, etc.), whereas neutron topography remains a unique tool for the investigation of magnetic crystals, and more specially the antiferromagnetic ones. The scope of X-ray topography, when coupled with synchrotron radiation, extended to unexpected topics through the use of coherent beams or by *in situ* experiments, where the material, in an adequate sample environment device, is imaged while an external parameter (temperature, stress, etc.) is changed. Some of the applications, of course, require a better spatial resolution. A possibility of overcoming this limitation is to use an X-ray lens to magnify the image before the detector. Promising attempts are being made using parabolic compound refractive lenses, asymmetrically cut crystals, or bent mirrors (Kirkpatrick-Baez setup).

Abstract

The basic principles of laser operation are presented starting with the semiclassical light-matter interaction model. Main properties of laser resonators and spatial modes are summarized. Laser amplifiers and laser oscillators operating in continuous-wave as well as in pulsed regimes, such as Q-switching and mode-locking, are discussed. The most important laser devices available today for industrial and scientific applications are also briefly presented.

Key points

- Pulsed laser regimes

Introduction

LASER is the acronym for Light Amplification by Stimulated Emission of Radiation. This Section and the next one will introduce the basic concepts in a most traditional way (Siegman 1986; Yariv 1989; Milonni and Eberly 2010; Svelto 2010). Stimulated emission can be obtained from a medium prepared in a non-thermal distribution of its energy-level populations (Fig. 1).

In a solid-state material, for example, this is achieved through the absorption of light at an appropriate pumping wavelength.

The laser medium can be practically everything, but for definiteness in the following reference is made to a solid-state matrix, contributing a background refractive index η , enclosing atoms which under pumping will be all set in a same final state, so that a homogenous lineshape of their laser transition is also understood, for simplicity. For the same reason, laser manifolds will not be considered and they will be treated as single levels. Since Nd:YAG is a widely used solid-state laser material, numerical examples will refer to it in the following.

A laser can be either an amplifier or an oscillator, in which an optical feedback is provided in order to allow the device to generate the laser beam from its own internally generated optical seed.

When a laser system is properly designed and operated, it is able to generate coherent light of extraordinary quality, in terms of spectral purity, directionality and power. The properties of the generated beam are precisely the reason of the importance of laser devices in scientific, biomedical, and industrial applications.

[☆]*Change History*: September 2022. A. Agnesi and G. Reali are involved in the revision. All figures have been reworked and uploaded. Few minor typos corrected in the main text. Sections "Laser types" and "Laser transients: Q-switching pulse generation" have been added (not present in the original chapter). Section "Laser transients: Mode-locking and ultra-short pulse generation" has also been a little expanded in its last part. Also the section "Conclusions" was added.

Fig. 1 Selective population inversion ($N_i > N_k$) deviating from thermal population distribution (dashed curve).

The basic interactions involved in laser operation proceed via the processes of (induced) absorption, spontaneous emission, and stimulated (or induced) emission. Spontaneous emission needs a quantum treatment, and in addition to providing, for a fraction of it, the seed into the right cavity mode that can start the laser action, represents an incoherent and completely uncorrelated contribution with respect to the coherent stimulated terms, and ultimately, it is responsible for the phase and amplitude fluctuations of laser systems.

For the induced processes instead, it is possible to resort to much simpler balance equations, first devised by Einstein, that describe how light is transported through the system. The basic idea of transport or rate equations approach is to add or subtract the quasi-resonant photon energies $\hbar\omega$ from the field as it travels through the atomic population, of densities N_2 , N_1 , that make transitions between levels separated by $\hbar\omega_0$. This is schematically shown in Fig. 2.

Accordingly, the incident optical intensity S (energy per unit area per unit time), that sweeps across a volume of unit cross-sectional area and thickness dz , containing $N_2 dz$ and $N_1 dz$ atoms in upper and lower levels interested by the interaction, will be changed as

$$\frac{\partial S}{\partial z} + \frac{1}{c} \frac{\partial S}{\partial t} = \sigma(N_2 - N_1)S \quad (1)$$

where σ (in units of length^2) is the induced transition cross-section, equal for both the events. The overall change in (1) will be according to the sign of $(N_2 - N_1)$. For positive sign, the medium behaves as an amplifier of light, while in the opposite case of negative population inversion, that is under ordinary thermal equilibrium conditions, only absorption can be realized and the optical intensity decreases in going across the medium.

In recognition of the amplifier condition, it is usual to define the gain coefficient (in units of length^{-1}) as

$$g = \sigma(N_2 - N_1) \quad (2)$$

so that, considering a steady-state ($\partial/\partial t = 0$) situation in (1),

$$\frac{dS}{dz} = gS. \quad (3)$$

In case of constant gain coefficient, equation (3) is easily solved, giving an exponential optical intensity growth,

$$S(z) = e^{gz} S(0). \quad (4)$$

An amplifier medium is used in laser oscillators, which are the basic laser devices. In their simplest configuration, they are set up enclosing the gain medium in a linear cavity formed by two (plane or curved) mirrors as shown in Fig. 3, of which one, of partial reflectivity R , provides the useful output coupling.

Fig. 2 Schematic of the interaction of two atomic levels with a quasi-resonant photon flux for an allowed transition.

Fig. 3 Optical laser cavity, with the pictorial description of its operation. Only almost axially emitted photons are trapped inside it.

The purpose is to trap only the almost axially emitted part of spontaneous emission seeds and redirect it along the axis so that it can be amplified and filtered through the combined action of the stimulated emission in the gain medium and the selective modal structure of the optical cavity. These iterated actions build up the self-sustained intense, highly monochromatic and directional laser beam. A simple gain-loss balance analysis of the mode in the optical cavity (or resonator) immediately provides the threshold lasing condition. Following the history of gain and losses of the oscillating mode along a full round-trip, and requiring self-reproducibility at the end of it, results:

$$e^{2g\ell} R(1 - L_i) = 1. \quad (5)$$

where ℓ is the gain medium length, R is the output coupling mirror reflectivity, and L_i are the double-pass passive cavity losses. This defines the threshold gain for the laser oscillator:

$$g_{th} = -\frac{\ln(R) + \ln(1 - L_i)}{2\ell}, \quad (6)$$

above which stimulated laser action initiates. A second important condition, which sets a constraint on the change of phase of the oscillating mode after a round-trip, will be derived later.

Creating population inversion and laser beam properties

In order to create a population inversion, the closed two-level system illustrated in Fig. 2 cannot work “as is,” since the nature of up-down stimulated transitions and their relation (same cross-section) prevents the possibility of using the same channel for both excitation and generation, in case of optical pumping. The minimum number of required levels is thus three, and a more general four-level system may perform even better, depending on the relative magnitudes of the relaxation rates of the level populations and on the selective actions of the pumping system. Fig. 4 clarifies the kinematics of the level populations in a four-level system.

In the most favorable case, a four-level system is one in which upper laser level 2 is fed at a rate that almost coincides with the rate at which level 3 is fed, due to a very fast, nonradiative relaxation from 3 to 2; in addition, the lower laser level 1 is constantly drained off, keeping it essentially empty, by its fast decay to lower laying levels.

Pumping efficiency and resonator design are the most important problems in laser engineering, since on their optimization depend the properties of the generated laser beam. (Thermal effects handling is also another important issue of high power laser systems).

Once the active medium has been chosen, and the application the laser is aimed at has suggested the operating regime (continuous wave, long pulses, short pulses, etc. . .), power, monochromaticity and spectral purity, coherence and directionality are essentially controlled by pumping and by the optical resonator. An overall parameter which can be used, for example, to

Fig. 4 A four-level laser, with the indication of the most relevant energy exchanges: the pump, and the fast decays into the upper laser level and out of the lower laser level, which favor an efficient creation of the population inversion.

compare laser light and standard generated light (Sun, lamp, discharge, etc. . .), is the brightness which summarizes all the above properties.

As a rule, laser emission is not at a single frequency near the ω_0 of the laser transition. Because of natural lifetime and interactions of the active atoms with the surrounding environment, gain effects, and photon lifetime, there is a sizable spectral broadening $\Delta\omega$ of the emitted light. Still, laser light is far better than all other light sources. As an example, Nd:YAG, one of the most widely used solid-state laser materials, lases at 1064 nm, corresponding to $\omega_0 \approx 1.8 \times 10^{15} \text{ s}^{-1}$, and may have spectral purity $\Delta\omega/\omega \approx 10^{-9}$ or better, several order of magnitudes smaller than any unfiltered thermal light source, for which that figure approaches 1.

Since the stimulated emission forces all photons in exactly the same quantum state, coherence persists until the radiating polarization, set up in the laser material, remains temporally and spatially correlated, and is not disturbed by any spurious effects like collisions with the environment. Collisions essentially determine the coherence time, which is connected to the degree of monochromaticity of the emitted light, $\tau_{coh} \approx 1/\Delta\omega$.

To a large extent, spatial coherence is formed by the transverse modal structure of the resonator, from which the beam derives its directionality. Spatial coherence and directionality are the properties that allow the beam to be brought, with very low spill-out energy, to a tight focus, an essential requirement in most laser applications. Diffraction theory shows that the lowest order, Hermite-Gauss mode of a stable resonator diverges with an angle $\vartheta_{0x} = \lambda/(\pi w_{0x})$, where w_{0x} is the beam waist (its lowest radius) in a x -direction perpendicular to z -propagation direction; a same expression holds for the y -direction. This is the lowest divergence among beams with same beam waist. It can be shown that higher order modes (and, more generally, a real beam made up of a mixture of these) with same waist diverge with an angle $\Theta_x = M_x^2 \vartheta_{0x}$, greater than the lowest order mode by a factor of M_x^2 , called the spatial beam quality factor (Koechner 2006); this expression can be used as an operative definition of the factor M_x^2 , which always is >1 for any real beam (a same expression holds for the y -direction).

High intensities and low divergence can be put together to define laser brightness, the power emitted per unit area per unit solid angle. The concept applies in general to any source of radiation; in case of lasers, it assumes a very simple form:

$$B = \frac{P}{A \times \Omega} \sim \frac{P}{(w_{0x}w_{0y})(\Theta_x\Theta_y)} \sim \frac{P}{\lambda^2 (M_x^2 M_y^2)} \quad (7)$$

and can be used as an indicator of the laser quality.

The fact that laser brightness is directly proportional to power is one of the reasons for research in the area of short and ultrashort pulse generation. Another reason is that very short pulses allow to investigate very short phenomena, in the same way as very small spots allow to see and work out very small details.

Interaction of light with matter

In order to understand the mechanisms that govern the generation of laser light, it is useful to analyze in some detail the results of the semi-classical treatment of light-matter interaction, using a simple two-level system as toy model (Yariv 1989; Milonni and Eberly 2010).

An incident optical field $\vec{E}(\vec{r}, t)$ on a quantum system, possessing a set of stationary levels and eigenfunctions, $\{E_i, \phi_i(\vec{r})\}$, is assumed to be almost resonant with two levels 2 and 1 with energy separation $\hbar\omega_0 = (E_2 - E_1)$, so that all the other levels can be ignored. Levels 2 and 1 are also assumed to have a well defined parity, and to be connected by a dipole-allowed transition. The time-dependent interaction is described by the second term of the hamiltonian $H = H_0 + H_1$, where, in the dipole approximation, $H_1 = -\vec{p} \cdot \vec{E}$ and the optical field is linearly polarized along $\hat{e}$ and has the form $\vec{E} = \hat{e}E_0(t) \cos(\omega t)$ with a slowly time-varying amplitude.

The solution is assembled in the form $\psi(\vec{r}, t) = c_1(t)\phi_1(\vec{r}) + c_2(t)e^{-i\omega t}\phi_2(\vec{r})$. Defining the dipole matrix elements $\vec{p}_{ij} = \int d^3r \phi_i^*(\vec{r}) \vec{p} \phi_j(\vec{r})$, neglecting rapidly varying terms, introducing the detuning $\Delta = (\omega_0 - \omega)$, and the Rabi frequency $\Omega = (\vec{p}_{ij} \cdot \hat{e})E_0(t)/\hbar$, the amplitude equations result:

$$\begin{aligned} i \frac{dc_1}{dt} &= -\frac{1}{2} \Omega^* c_2 \\ i \frac{dc_2}{dt} &= \Delta c_2 - \frac{1}{2} \Omega c_1 \end{aligned} \quad (8)$$

These are used to form the set of equations obeyed by the density matrix

$$\rho = \begin{bmatrix} \rho_{11} & \rho_{12} \\ \rho_{21} & \rho_{22} \end{bmatrix} = \begin{bmatrix} c_1 c_1^* & c_1 c_2^* \\ c_2 c_1^* & c_2 c_2^* \end{bmatrix}. \quad (9)$$

with closure condition $\rho_{11} + \rho_{22} = |c_1|^2 + |c_2|^2 = 1$, which provides a most compact means to calculate the expectation values of quantum observables, $\langle A \rangle = \text{Tr}\{\rho A\}$. In their final form, the equations for the ρ_{ij} are:

$$\begin{aligned}
\frac{d\rho_{11}}{dt} &= -\frac{i}{2}(\Omega\rho_{12} - \Omega^*\rho_{21}) \\
\frac{d\rho_{22}}{dt} &= -\frac{d\rho_{11}}{dt} \\
\frac{d\rho_{12}}{dt} &= i\Delta\rho_{12} + \frac{i}{2}\Omega(\rho_{22} - \rho_{11})
\end{aligned} \tag{10}$$

These equations describe the evolution of the laser population densities and of the induced polarization in a material, introduced through the macroscopic variables:

$$\begin{aligned}
N_1 &= N\rho_{11} \\
N_2 &= N\rho_{22} \\
\vec{P} &= N \int d^3r \psi^*(\vec{r}) \vec{p} \psi(\vec{r}) = N(\rho_{12}\vec{p}_{21}e^{-i\omega t} + c.c.)
\end{aligned} \tag{11}$$

with N the total population density participating in the interaction, and where $\vec{p}_{ii} = 0$ has been used. Introducing the slowly varying macroscopic polarization, $\vec{P}(t) = 1/2[\hat{E}P(t)e^{-i\omega t} + c.c.]$, and comparing it with the third of equations (11),

$$P(t) = 2N(\vec{p}_{12} \cdot \hat{E})\rho_{21} \tag{12}$$

is obtained. The macroscopic equations thus result:

$$\begin{aligned}
\frac{dN_1}{dt} &= -\frac{1}{2\hbar} \text{Im}(E_0^*P) = -\frac{dN_2}{dt} \\
\frac{dP}{dt} &= -i\Delta P - i \frac{|\vec{p}_{12} \cdot \hat{E}|^2}{\hbar} (N_2 - N_1)E_0
\end{aligned} \tag{13}$$

These equations describe the dynamics of an ensemble of isolated two-level atoms. In this form, they do not yet reflect some very important features that extend this ensemble into a working model of laser, such as the existence of relaxation processes through collisions or radiative decays, and especially the possibility of pumping energy into the system to get population inversion, $(N_2 - N_1) > 0$. The inclusion of these physical effects is possible by making a phenomenological fix of the equations (13) based on physical considerations; this is illustrated in Fig. 5.

The main effects to be included are: (i) pumping rates into levels 2 and 1, R_2 , and R_1 , respectively; (ii) dampings of levels 2 and 1 due to inelastic collisions and radiative decays, γ_2 and γ_1 , respectively; (iii) damping due to elastic collisions, which only affect induced polarization, γ_{ph} . Taking all these effects into account leads to:

$$\begin{aligned}
\frac{dN_1}{dt} &= R_1 - \gamma_1 N_1 - \frac{1}{2\hbar} \text{Im}(E_0^*P) \\
\frac{dN_2}{dt} &= R_2 - \gamma_2 N_2 + \frac{1}{2\hbar} \text{Im}(E_0^*P) \\
\frac{dP}{dt} &= -(\gamma + i\Delta)P - i \frac{|\vec{p}_{12} \cdot \hat{E}|^2}{\hbar} (N_2 - N_1)E_0,
\end{aligned} \tag{14}$$

where $\gamma = \gamma_{ph} + (\gamma_1 + \gamma_2)/2$ is the damping rate for the induced polarization.

Fig. 5 Pumping and decays that make the “two-level” model a “real” laser model.

1 Rate-equation approximation and the laser amplifier

It happens quite often that in laser materials γ is much larger than all the other rates, so that the induced polarization rapidly reaches a steady-state and follows adiabatically the changes of the field and the atomic populations. In this "rate-equation approximation", it is possible to set $dP/dt = 0$, resulting in:

$$P(t) = -i \frac{|\vec{p}_{12} \cdot \vec{\epsilon}|^2}{\hbar(\gamma + i\Delta)} (N_2 - N_1) E_0(t). \quad (15)$$

This can be substituted back into the population equations to give the final rate equations (Siegman 1986; Yariv 1989; Koechner 2006; Milonni and Eberly 2010; Svelto 2010):

$$\begin{aligned} \frac{dN_1}{dt} &= R_1 - \gamma_1 N_1 + W(N_2 - N_1) \\ \frac{dN_2}{dt} &= R_2 - \gamma_2 N_2 - W(N_2 - N_1) \\ W &= \frac{\pi |p_{12}|^2 |E_0(t)|^2}{6\hbar^2} \frac{\gamma/\pi}{\gamma^2 + \Delta^2} \end{aligned} \quad (16)$$

A factor of 3, due to angular averaging, has been included in the last of (16) to account for random local dipole orientations with respect to the electric field, $|\vec{p}_{12} \cdot \vec{\epsilon}|^2 = |p_{12}|^2/3$.

It is recognized that the expression of W , which represents the rate at which the inversion is changed, can be written as:

$$W = \frac{\sigma S}{\hbar\omega}, \quad (17)$$

where the photon flux is

$$\frac{S}{\hbar\omega} = \frac{c\epsilon_0\eta |E_0(t)|^2}{\hbar\omega}$$

and where η is the average, background refractive index of the material. From (17) the expression for the induced transition cross-section is obtained:

$$\sigma = \frac{\pi |p_{12}|^2 \omega}{6c\epsilon_0\eta\hbar} \frac{\gamma/\pi}{\gamma^2 + \Delta^2}. \quad (18)$$

A quantum mechanical calculation of the spontaneous emission rate A provides the explicit form:

$$A = \frac{1}{\tau_{sp}} = \frac{\omega_0^3 \eta |p_{12}|^2}{3\pi\epsilon_0\hbar c^3}, \quad (19)$$

which, used in (18) to eliminate $|p_{12}|^2$, with the consideration that $\gamma \ll \omega_0$, leads to the most popular form of the transition cross-section ($\lambda = \lambda_0/\eta$ is the laser wavelength in the laser material):

$$\sigma(\omega) = \frac{\lambda^2}{8\tau_{sp}} \frac{\gamma/\pi}{\gamma^2 + \Delta^2} = \frac{\lambda^2}{8\tau_{sp}} \mathcal{L}(\omega). \quad (20)$$

$\mathcal{L}(\omega)$ is the normalized Lorentzian lineshape, obtained in the homogeneous broadening hypothesis. This expression can be used, for example, to get a numerical estimate of the cross-section of Nd:YAG using available data, $\tau_{sp} = 230 \mu\text{s}$, $\gamma = 2\pi \times 120 \text{ GHz}$, $\eta = 1.82$. The computation gives $\sigma \approx 3.5 \times 10^{-19} \text{ cm}^2$, which catches with its most quoted value, a good result for this simple model.

Thus, the laser gain introduced in equation (2) results

$$g(\omega) = \frac{\lambda^2}{8\tau_{sp}} \mathcal{L}(\omega) (N_2 - N_1). \quad (21)$$

In more general and realistic situations, the lineshape has different widths and shapes, and can be largely inhomogeneous, if all the atoms do not have the same center transition frequency (as, for example, in Nd:glass).

From rate equations, it is immediately clear that the population inversion depends on optical intensity S , since W depends on it. In a strict four-level system, previously illustrated, in which pumping into lower laser level is suppressed, $R_1 = 0$, and the decay from the lower laser level is assumed to be very fast, these rate equations unveil this feature very clearly, when solved for the steady-state. The result in this case is:

$$N_2 - N_1 = \frac{R_2/\gamma_2}{1 + S/S_{sat}} = \frac{(N_2 - N_1)_0}{1 + S/S_{sat}}, \quad (22)$$

where $(N_2 - N_1)_0 = R_2/\gamma_2$ is the inversion at low optical intensity, when $S/S_{sat} \ll 1$, and $S_{sat} = (\hbar\omega\gamma_2/\sigma)$ is the saturation intensity. The gain thus becomes:

$$g(\omega) = \frac{\sigma(\omega)(N_2 - N_1)_0}{1 + S/S_{sat}} = \frac{g_0(\omega)}{1 + S/S_{sat}}. \quad (23)$$

where the small signal gain g_0 has been introduced with an obvious identification.

An immediate application of (23) is its use into (3) to obtain the general behavior of a single-mode amplifier. The equation

$$\frac{dS}{dz} = \frac{g_0(\omega)}{1 + S/S_{sat}} S. \quad (24)$$

has general solution of the following form:

$$\frac{S(z) - S(0)}{S_{sat}} + \ln\left(\frac{S(z)}{S(0)}\right) = g_0 z. \quad (25)$$

where $S(0)$ is the input intensity. The exponential growth of equation (4) is thus obtained only for intensities small compared with the saturation intensity. At the opposite limit, when the first term of the left-hand side of (25) dominates, the intensity difference grows only linearly with the length, as $g_0 S_{sat} z$. If multiplied by the effective area A_{eff} of the beam, and noting that $P_{ex} = g_0 S_{sat} = R_2 \hbar\omega$ is the available power density from the gain medium, $g_0 S_{sat} A_{eff} z$ is seen to be the maximum extractable power from the amplifier, which is only attained working in saturation regime. In Fig. 6 the plots of the “growth rate” $= (1/S)(dS/dz)$ and the “power extraction rate” $= dS/dz$ show that the growth rate is maximum for small S and drops to zero for large S , while an exactly specular behavior is followed by the power extraction.

Finally, it is useful to summarize these considerations into the definition of a figure of merit for the amplifier, its internal efficiency:

$$\eta_{int} = \frac{S(z) - S(0)}{R_2 \hbar\omega_p z} = \frac{S(z) - S(0)}{R_2 \hbar\omega z} \frac{\hbar\omega}{\hbar\omega_p} = \frac{S(z) - S(0)}{R_2 \hbar\omega z} \eta_s. \quad (26)$$

where $P_p = R_2 \hbar\omega_p$ is the pump power density available in the amplifier, and η_s is the Stokes efficiency.

Laser resonators and beam modes

The importance and the advantages of making high quality beams are so overwhelming that laser research has dedicated a lot of efforts in studying optical resonators, which are the devices used to provide the oscillator feedback and to spatially shape the laser beams. In a laser, the cavity is set up of (flat or curved) mirrors, surrounding the gain medium, which select only the light emitted approximately along the resonator axis, and reflect it back and forth several times, thus providing the necessary feedback that sustains the laser action. What characterizes a laser from other coherent devices at longer wavelengths (in the far IR and microwave

Fig. 6 Growth rate and power extraction rate plots as a function of intensity normalized to the saturation intensity.

Fig. 7 Empty laser resonator used to discuss the modes of a stable cavity laser. R_1 and R_2 are the curvature radii of the two confining mirrors, one of which eventually has a partial reflectivity to allow outcoupling of the laser field.

ranges) is that an open resonator is needed to limit the number of possible oscillating modes which fits under the gain linewidth of the laser medium, and get temporally coherent radiation. In addition to the feedback action, the most important function of the resonator is the transverse spatial shaping of the radiated field, and the optical spatial quality of a beam is generated by using the transverse modal structure of the resonator. Optical resonators can be grouped into two classes: stable resonators are characterized by having closed ray paths, while unstable resonators have no closed paths, and are mainly used in high gain laser systems. Only stable resonators will be briefly described, while the book by Siegman (1986) provides a complete authoritative review on resonator subject. The empty linear resonator shown in Fig. 7 will be used to illustrate the sustained resonator modes.

With this geometry, it is possible to select the fundamental TEM_{00} mode because the higher-order modes suffer significantly greater losses.

The structure of these modes can be found by solving the wave equation, which governs the propagation of beams whose transverse (i.e., (x, y)) dependence is less rapid than their z -dependence. Recognizing these different spatial rates, the complex quasi-monochromatic field amplitude is written as

$$E(x, y, z, t) = E_0 u(x, y, z) e^{i(kz - \omega t)} \quad (27)$$

where the spatial shape $u(x, y, z)$ is a slowly varying function in its variables with respect to e^{ikz} , and satisfies the following parabolic wave equation (also known in optics as paraxial wave equation):

$$2ik \frac{\partial u}{\partial z} + \left(\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} \right) = 0 \quad (28)$$

It can be shown that, if a (unit amplitude) beam with Gaussian shape

$$u(x, y, 0) = \exp \left(-\frac{x^2 + y^2}{w_0^2} \right) \quad (29)$$

is chosen as initial condition at its narrowest point in $z = 0$ (w_0 is correspondingly called the beam waist), then the solution for arbitrary z is given by:

$$u(x, y, z) = \frac{1}{1 + i(2z/kw_0^2)} \exp \left(-\frac{x^2 + y^2}{w_0^2 + i2z/k} \right) \quad (30)$$

After defining new quantities (illustrated in Fig. 8): $z_0 = kw_0^2/2$, the Rayleigh range or confocal parameter; $R(z) = z + z_0^2/z$, the beam radius of curvature; $w(z) = w_0[1 + (z/z_0)^2]^{1/2}$, the beam radius; equation (30) can be put into the more transparent form:

$$u(x, y, z) = \frac{w_0}{w(z)} \exp \left(-\frac{x^2 + y^2}{w^2(z)} + ik \frac{x^2 + y^2}{2R(z)} - i \tan^{-1} \left(\frac{z}{z_0} \right) \right) \quad (31)$$

The fundamental, TEM_{00} mode of the laser beam is thus:

$$E_{00}(x, y, z, t) = E_0(t) e^{i(kz - \omega t)} \times \frac{w_0}{w(z)} \exp \left(-\frac{x^2 + y^2}{w^2(z)} + ik \frac{x^2 + y^2}{2R(z)} - i \tan^{-1} \left(\frac{z}{z_0} \right) \right) \quad (32)$$

Higher order transverse modes can also be found, and they are given, in terms of the complete Hermite-Gauss set functions, so that

$$E_{mn}(x, y, z, t) = E_0(t) e^{i(kz - \omega t)} H_m \left(\frac{\sqrt{2}x}{w(z)} \right) H_n \left(\frac{\sqrt{2}y}{w(z)} \right) \times \frac{w_0}{w(z)} \exp \left(-\frac{x^2 + y^2}{w^2(z)} + ik \frac{x^2 + y^2}{2R(z)} - i(m+n+1) \tan^{-1} \left(\frac{z}{z_0} \right) \right) \quad (33)$$

The first few transverse mode distributions are pictorially shown in Fig. 9.

Fig. 8 Geometrical meaning of the beam parameters defined in the text.

Fig. 9 Patterns of first low-order Hermite-Gauss modes.

Imagine now that the resonator of Fig. 7 has mirrors at $z_1 < 0$ and $z_2 > 0$, with radii of curvature $R_1 = -R(z_1)$, $R_2 = R(z_2)$, respectively. A point (x, y, z) on mirror 2 satisfies the equation

$$R_2^2 = x^2 + y^2 + (R_2 - z_2 + z)^2 \quad (34)$$

which can be rewritten as

$$z_2 - \frac{(z - z_2)^2}{2R_2} = z + \frac{x^2 + y^2}{2R_2} \quad (35)$$

The paraxial wavefront of constant phase φ almost coincides (within the lowest order) with the mirror at z_2 when evaluated on the mirror surface:

$$\varphi = k \left\{ z_2 - \frac{x^2 + y^2}{2R_2} - \frac{(z - z_2)^2}{2R_2} \right\} + k \frac{x^2 + y^2}{2R_2} - (m + n + 1) \tan^{-1} \left(\frac{z}{z_0} \right) - \omega t \quad (36)$$

and the beam strikes the mirrors perpendicularly and propagates back and forth along the cavity. The losses due to phase mismatch can be canceled by tuning the wave-number $k = \omega/c$ so that the total phase change of the beam between the mirrors is an integer number l of π :

$$l\pi = \frac{\omega L}{c} - (m + n + 1) \left\{ \tan^{-1} \left(\frac{z_2}{z_0} \right) - \tan^{-1} \left(\frac{z_1}{z_0} \right) \right\} \quad (37)$$

where $L = (z_2 + |z_1|)$ is the cavity length. The frequency satisfying (37) for given values of (l, m, n) is called ω_{lmn} (l is the longitudinal mode index; m, n are the transverse mode indices) and the corresponding field is called the TEM_{mn} transverse mode. The larger the transverse indices (m, n) are, the less the wavefronts coincide with the mirrors' curvatures, which means that there is the tendency (if not otherwise managed) to have larger losses and the suppression of higher order transverse modes in favor of the lowest order one. A change between two nearby longitudinal mode frequencies with same (m, n) is given by:

$$\Delta\omega_{lmn} = \omega_{(l+1)mn} - \omega_{lmn} = \frac{\pi c}{L} \quad (38)$$

while varying the transverse mode indices at fixed l results:

$$\delta\omega_{lmn} = \frac{c}{L} \delta(m+n) \left\{ \tan^{-1} \left(\frac{z_2}{z_0} \right) - \tan^{-1} \left(\frac{z_1}{z_0} \right) \right\} \quad (39)$$

where $\delta(m+n)$ is the change in $(m+n)$. It is not hard to see, for example, in the case when $z_0 \gg z_2, |z_1|$, that the transverse mode structure appears as a fine structure of the longitudinal mode spectrum.

It should be noted that, if the resonator is loaded with a gain medium of length ℓ , its length L must be replaced by the optical length $L' = L + (\eta - 1)\ell$, so that the phase condition (37) contains the refractive index of the gain medium $\eta(\omega, S)$, which depends on frequency as well as on laser beam intensity. This should alert that the exact longitudinal mode position is also a function of the working power of the laser.

Single mode continuous laser operation

Laser oscillators can be operated in various regimes. Some of them can be easily studied using the laser rate equations previously introduced:

$$\begin{aligned} \frac{dN_1}{dt} &= -\gamma_1 N_1 + \frac{\sigma S}{\hbar\omega} (N_2 - N_1) \\ \frac{dN_2}{dt} &= R_2 - \gamma_2 N_2 - \frac{\sigma S}{\hbar\omega} (N_2 - N_1) \\ \frac{\partial S}{\partial z} + \frac{1}{c} \frac{\partial S}{\partial t} &= \sigma S (N_2 - N_1) - \frac{\gamma_c}{c} S + \frac{R_{sp}}{c} \end{aligned} \quad (40)$$

where the added spontaneous emission rate R_{sp} reminds the origin of the starting laser seed, and a loss term for the laser field has been inserted to account for both useful mirror output coupling and residual, undesirable losses due to intracavity absorption and scattering. According to (6), these are collectively given by

$$\frac{\gamma_c}{c} = -\frac{\ln(R) + \ln(1 - L_i)}{\ell} \approx \frac{(1 - R) + L_i}{\ell}, \quad (41)$$

where the last expression applies in the low-loss limit. In many common situations the intensity S is approximately uniform along the cavity axis. Assuming this approximation, and taking into account the different lengths of the gain medium, ℓ , and of the cavity, L , the final form of (40) becomes:

$$\begin{aligned} \frac{dN_1}{dt} &= -\gamma_1 N_1 + \frac{\sigma S}{\hbar\omega} (N_2 - N_1) \\ \frac{dN_2}{dt} &= R_2 - \gamma_2 N_2 - \frac{\sigma S}{\hbar\omega} (N_2 - N_1) \\ \frac{dS}{dt} &= \frac{c\sigma\ell}{L} S (N_2 - N_1) - \gamma_c S + R_{sp} \end{aligned} \quad (42)$$

which are the single-mode rate-equations (Siegman 1986; Yariv 1989; Koechner 2006; Svelto 2010; Milonni and Eberly 2010).

Under steady-state conditions, the rates of change of both population inversion and intensity is set to zero, and neglecting the small R_{sp} contribution, from (42) it follows:

$$\begin{aligned} g(\omega, S) &= \frac{g_0(\omega)}{1 + S/S_{sat}} \\ 0 &= \left[\frac{c\ell}{L} g(\omega S) - \gamma_c \right] S \end{aligned} \quad (43)$$

where the first equation gives the saturated gain already derived in (23), with $S_{sat} = \hbar\gamma_2/\sigma$, and $g_0 = \sigma(N_2 - N_1)_0 = \sigma R_2/\gamma_2$. Below threshold the optical intensity remains zero until the pumping rate has grown high enough to bring the small signal gain at the threshold. Thus, g_0 grows linearly with the pump rate, and at threshold it results:

$$\begin{aligned} \frac{c\ell}{L} g_{th} &= \frac{c\ell}{L} g_{0th} = \frac{c\ell}{L} \frac{\sigma R_{2th}}{\gamma_2} = \gamma_c \\ R_{2th} &= \frac{L}{c\ell} \frac{\gamma_2 \gamma_c}{\sigma} \end{aligned} \quad (44)$$

Above threshold, $g(\omega, S)$ remains clamped to its threshold value, since $S \neq 0$ and, under the steady-state hypothesis, it cannot be

$$\left[\frac{c\ell}{L} g(\omega, S) - \gamma_c \right] S > \left[\frac{c\ell}{L} g_{0th} - \gamma_c \right] S = 0. \quad (45)$$

Thus it follows that

$$\frac{g_0}{1 + S/S_{sat}} = g_{0th}. \quad (46)$$

and, for the internal intensity,

$$S = S_{sat} \left(\frac{g_0}{g_{0th}} - 1 \right) = S_{sat} \left(\frac{R_2}{R_{2th}} - 1 \right). \quad (47)$$

Far above threshold, this becomes $S \approx (\ell/L)(cR_2\hbar\omega/\gamma_c)$.

The resonator output intensity is, in the low-loss limit of (41):

$$S_{out} = (1 - R)S = \frac{\ell}{L}(1 - R)S_{sat} \left[\frac{2g_0\ell}{(1 - R) + L_i} - 1 \right]. \quad (48)$$

which is plotted in Fig. 10 as a function of the output coupling T .

The factor of 2 multiplying the gain coefficient is due to the fact that in a two-mirror resonator the gain medium is traversed twice per round-trip.

From this figure it is clear that there is an optimum working point, obtained maximizing S_{out} with respect to the output coupling at fixed small signal gain (that is, at fixed pump rate):

$$\begin{aligned} T^{opt} &= L_i \left(\sqrt{\frac{2g_0\ell}{L_i}} - 1 \right) \\ S_{out}^{opt} &= \frac{\ell}{L} S_{sat} \left(\sqrt{2g_0\ell} - \sqrt{L_i} \right)^2, \end{aligned} \quad (49)$$

which represents the working condition for well-engineered continuous wave laser systems.

Laser types: Important laser active media

In this Section, an overview of laser materials is provided (Svelto 2010). Laser action has been demonstrated from X-rays to THz domain, while the first historical demonstration of electromagnetic radiation amplification by stimulated emission was done with a microwave device, a “maser.”

Free-electron lasers (FELs) actually exploit a kind of coherent radiation amplification which cannot be strictly modeled as it was done in the previous Sections, for a general four-level or three-level laser. In FELs a beam of relativistic electrons is sent through a periodic, spatially-modulated orthogonal magnetic field which causes transversal charge acceleration, producing narrow-angle radiation emission in the beam direction. FELs are complex, yet unique scientific tools for production of intense beams of spatially

Fig. 10 Output intensity as a function of outcoupling transmission.

and temporally coherent radiation from a resonant cavity, at wavelengths not accessible with other laser technologies, especially on the short-wavelengths side of the electromagnetic spectrum. Additionally, tuning parameters such as electrons speed and magnetic field strength make FELs the most broadly tunable source of coherent radiation, in principle, from X-rays to far-infrared.

Excimer lasers are traditionally important for UV radiation generation, which finds applications in microelectronics and surgery. As in most gas lasers the excitation occurs through electric discharge, in this particular case producing transient “artificial” molecules of rare gases and halogens such as XeCl, KrF, etc. which decay in short (picosecond) time releasing an UV photon. These lasers usually work at atmospheric pressure to produce high energy UV pulses up to multi-kHz repetition rate.

Although the visible spectrum was covered for a long time by gas lasers such as Ar-ions, Kr-ions, copper-vapors and HeNe, exploiting dipole-allowed electronic transitions, in the last decades solid-state and semiconductor laser technologies became more popular for many applications due to their higher efficiency and reliability, less expensiveness, maintenance-free operation and greater compactness of the devices.

Semiconductor lasers are now commercially available with wavelength ranging from the UV to the THz. In these devices an electrical current produces coherent radiation at junctions between different types of semiconductors, through carrier recombination, often exploiting the advantages of quantum well structures at the junction. Electronic transitions can be either interband (for the most energetic photons, UV to near-infrared) or intraband, like in quantum cascade lasers (wavelengths $>2\ \mu\text{m}$). Semiconductor laser engineering allows to design practical devices which can emit at any desired wavelength in this broad range. However, single-spatial-mode emission as well as single-frequency operation is possible only for modest power $<1\ \text{W}$, whereas more powerful devices (up to hundred watts) needed for medical and industrial applications have increasingly poor beam quality.

Thus high-power semiconductor lasers at convenient wavelengths are frequently used to pump solid-state lasers, which in turn act as brightness amplifiers, absorbing very-low-spatial-quality radiation and emitting diffraction-limited radiation at longer wavelength, normally at good efficiency, up to $\sim 90\%$ in some cases.

A particular technology implementing a multiwatt semiconductor laser with excellent spatial and spectral features is the optically-pumped semiconductor laser: an ordinary current-driven high-power multimode semiconductor laser pumps a semiconductor disk in a laser resonator, with a mode size $\sim \sqrt{\lambda L}$ allowing both multiwatt operation and diffraction-limited performance. Intracavity second harmonic generation with nonlinear crystals is generally exploited to reach the visible range, with excellent power stability performance unlike solid-state lasers. These are potentially affected by relaxation oscillations started by the nonlinear conversion process due to their long fluorescence lifetime.

Solid-state lasers are workhorse technology for most industrial, medical and scientific applications. Rare-earth ions such as Nd^{3+} and Yb^{3+} (four-level and quasi-three-level, respectively), with suitable hosts (typically crystals like YAG, YVO_4 and many others) are used for laser emission at $\sim 1\ \mu\text{m}$ wavelength, where sources up to $\sim \text{kW}$ -class (continuous-wave) and $\sim 100\ \text{W}$ average power in pulsed operation (either nanosecond, picosecond and even femtosecond pulse duration) are available commercially for demanding industrial applications. $\text{Er}^{3+}/\text{Yb}^{3+}$ solid-state three-level lasers are used mainly for laser ranging and medical applications at the eyesafe wavelength around $1.5\ \mu\text{m}$. Tm^{3+} and Ho^{3+} three-level lasers emit light at $\sim 2\ \mu\text{m}$ which is an important wavelength for laser surgery (strong absorption by water and organic tissues). Additionally they are becoming increasingly important for mid-IR technology, also through wavelength extension using optical parametric generation with nonlinear crystals.

Vibronic laser materials based on transition metal ions like $\text{Ti}^{3+}:\text{Al}_2\text{O}_3$ and $\text{Cr}^{2+}:\text{ZnSe}$ or $\text{Cr}^{2+}:\text{ZnS}$ exploit exceptional spectral broadening due to strong electron-phonon interactions. They feature the broadest tuning range of $\sim 0.65\text{--}1.1\ \mu\text{m}$ and $\sim 2\text{--}3.5\ \mu\text{m}$, respectively, allowing direct generation of the shortest pulses possible from a given laser material. $\text{Ti}^{3+}:\text{Al}_2\text{O}_3$ lasers are very common tools for ultrafast science, enabling a variety of advanced applications including ultrafast spectroscopy, nonlinear microscopy and precision metrology with frequency combs. Cr^{2+} -doped lasers extend such concepts and technologies to the mid-IR, also enabling important new sensing applications.

A most remarkable technology is that of fiber lasers, based on either Yb^{3+} ($\sim 1\ \mu\text{m}$ wavelength range), $\text{Er}^{3+}/\text{Yb}^{3+}$ ($\sim 1.5\ \mu\text{m}$), or $\text{Tm}^{3+}/\text{Ho}^{3+}$ ($\sim 2\ \mu\text{m}$). Although “solid-state” in nature, waveguiding in optical fibers enables high compactness, robustness and alignment-free operation, as well as the ability to manage high-power absorption over long lengths. These features spurred a quick and extraordinary development of the fiber laser technology in the last 20 years.

As a side note, the huge market for telecom application ($\sim 1.5\ \mu\text{m}$ wavelength range) drove fast and exceptional development of fiber- and semiconductor-laser technologies in the 1990s, which greatly benefited many other industries, for example, making available laser diodes of increasing reliability and performance for pumping solid-state lasers.

Presently, fiber lasers are challenging solid-state laser technology also in many traditional applications where pulsed laser emission is required, and for which they were intrinsically limited due to the difficulty to propagate intense pulses (of nanosecond or picosecond duration) in small fiber cores. In fact, recent developments of special photonic-crystal fibers, with increasingly large mode area, or hollow fibers, in which the pulse propagates in air, are dramatically reducing the performance gap with traditional solid-state laser technology in these increasingly expanding area of applications.

Finally, kW-class continuous-wave Yb^{3+} fiber laser has become nowadays the technology of choice for the heaviest industrial applications such as in the automotive, in many cases replacing or completely displacing away CO_2 lasers (another notable example of gas laser, based on molecular vibrational transitions at $\sim 10\text{-}\mu\text{m}$ wavelength).

Laser transients: Q-switching pulse generation

In this Section and the next one, time-dependent, transient laser effects are briefly discussed. There are distinctly two ways to generate powerful pulses, and which one is chosen depends on applications.

When high power and high energy are required, Q-switching operation is the preferred technique. This consists in keeping the Q of the optical cavity low at the beginning of the pump action, so that the population inversion can grow to a very high level. When this is achieved, the cavity Q is suddenly restored to its original value, allowing an abrupt growth of the field to a high power concentrated in a short pulse. Q-switching can be discussed within the single-mode approximation of the previous paragraph using the equations (42), even if fast transients always tend to bring many longitudinal modes into oscillation. Generally this technique leads to nanosecond pulse durations, with single-pulse energies up to several hundreds of millijoules or even joules.

Since the growth of the laser pulse starting from spontaneous emission, as well as the gain dynamics, are fast with respect to both fluorescence decay and pump rate (for continuous-wave pumping), the equations (42) describing single-mode Q-switching in a linear, standing-wave resonator can be simplified as (Siegman, 1986; Koechner, 2006)

$$\frac{d\Gamma}{dt} = -\frac{S}{S_{sat}}\Gamma \quad (50)$$

$$T_R \frac{dS}{dt} = (2\Gamma - L_i - \ln(1/R))S \quad (51)$$

with $\Gamma = \int g dz$ being the single-pass unsaturated gain exponent, integrated along the amplifier. T_R is the round-trip time.

Here we concentrate on active Q-switching, where loss modulation is basically instantaneous, and is provided by an electrical modulator (typically electro-optic or acousto-optic).

Assuming continuous-wave pumping, in general, these equations can be readily solved to give the output pulse energy E_o and the pulse duration τ_o :

$$E_o = E_{sat} \frac{\ln(1/R)}{L_i + \ln(1/R)} (\Gamma_i - \Gamma_f) \quad (52)$$

$$\tau_o = \frac{\Gamma_i - \Gamma_f}{\Gamma_i - \Gamma_{th} [1 + \ln(\Gamma_i/\Gamma_{th})]} T_c \quad (53)$$

being Γ_i the initial gain when Q-switching occurs, Γ_f the residual gain after the pulse is emitted, $2\Gamma_{th} = L_i + \ln(1/R)$ the threshold gain for continuous-wave operation, and $T_c = T_R/[L_i + \ln(1/R)]$ the photon lifetime in the un-pumped resonator. The saturation energy is $E_{sat} = S_{sat} A \tau_{sp}$, where A is the beam cross section in the amplifier.

A third equation relates initial and final gains:

$$\Gamma_i - \Gamma_f + \Gamma_{th} \ln(\Gamma_f/\Gamma_i) = 0 \quad (54)$$

Integrating the difference of the first two equations (42), to give the time evolution of the population inversion between two Q-switching pulses, one finds a fourth equation, which allows to eventually calculate Γ_i and Γ_f :

$$\Gamma_i = \Gamma_0 - (\Gamma_0 - \Gamma_f) \exp\left(-\frac{1}{f\tau_{sp}}\right) \quad (55)$$

where f is the repetition rate of the Q-switching pulses, determined by the active modulator. Γ_0 is clearly the gain at $f = 0$, due to the continuous-wave pump rate R_2 .

Since in general all lasers are designed to operate well above threshold, in continuous-wave regime, we may assume $\Gamma_0 \gg \Gamma_{th} > \Gamma_f$, yielding a simple expression for the pulse energy as a function of f :

$$E_o \sim E_{sat} \Gamma_0 \eta_o \left[1 - \exp\left(-\frac{1}{f\tau_{sp}}\right) \right] \quad (56)$$

where $\eta_o = (\ln(1/R))/(L_i + \ln(1/R))$ is the output coupling efficiency. At low repetition rate, the preferred regime for high-energy Q-switched lasers, $f \ll 1/\tau_{sp}$, $\Gamma_i \sim \Gamma_0$ and the output pulse energy and duration is $E_o \sim E_{sat} \Gamma_0 \eta_o$ and $\tau_o \sim T_c$, respectively.

High-frequency Q-switching is used instead for many industrial applications such as fast material processing and laser sensing. In this regime $f \gg 1/\tau_{sp}$ and one can use a convenient asymptotic approximation of equations (52) and (53) to obtain the key laser parameters:

$$E_o \sim \frac{E_{sat} \Gamma_0}{f\tau_{sp}} \quad (57)$$

$$\tau_o \sim \frac{8T_R\tau_{sp}}{\Gamma_0} f \quad (58)$$

However, there exists a maximum possible frequency f , which is related to the build-up time of the pulse from starting noise, which is emitted isotropically and is amplified most effectively along the solid angle determined by the amplifier length and the cross-section of the pumped region. In general, it turns out that

$$\tau_b = \frac{25T_c}{\Gamma_0/\Gamma_{th} - 1} \quad (59)$$

This is generally one order of magnitude longer than the pulse width. Applying again the high-frequency approximation, τ_b becomes

$$\tau_b \sim \frac{50T_R\tau_{sp}}{\Gamma_0} f \quad (60)$$

The obvious condition that must be satisfied is $\tau_b < 1/f$, which eventually sets the highest frequency of operation:

$$f < \sqrt{\frac{\Gamma_0}{50T_R\tau_{sp}}} \quad (61)$$

It is thus seen that the pulse duration increases proportionally to f , and the energy decreases like $1/f$.

A completely different behavior is obtained with passive Q-switching. In this case, a saturable absorber is used instead of an electric modulator.

Saturable absorbers most frequently employed for Q-switching are Cr:YAG crystals (for 1- μm lasers) and SESAMs (SEmiconductor Saturable Absorber Mirrors), which will be mentioned also for the generation of much shorter pulses, in the next Section.

If proper material and laser design conditions are met, such nonlinear absorber saturates its losses before the laser amplifier is depleted, providing a relatively slow but effective Q-switching action. This kind of Q-switching will not be described in detail here, however the most important results are summarized as follows:

- the pulse energy is constant, $E_o \sim AS_{sat}\tau_{sp}2q_0$, basically fixed by the round-trip saturable loss modulation q_0
- pulse width is also constant, $\tau_o \sim 3.5T_R/q_0$
- pulse repetition rate increases linearly with pump power
- a maximum repetition frequency exists also in this case, due to $\tau_b < 1/f$

It is clear that relatively short pulses down to ~ 100 ps can be more easily generated with microchip lasers ($T_R \sim$ few picoseconds) operating in passive Q-switching, with the unique advantage of constant pulsewidth over their frequency range. In fact, the smallest electric modulators allows miniature Q-switched lasers as short as few centimeters, giving pulse duration slightly longer in principle: since in this last case $\tau_o \sim T_c$, pulses as short as few hundreds picosecond are still possible, but the duration increases with the frequency.

A consequence of (61) (and a similar expression for passive Q-switching) is that repetition rates as high as ~ 1 MHz are possible with very short laser resonators.

Laser transients: Mode-locking and ultra-short pulse generation

In this Section, a different technique is discussed for the generation of ultra-short pulses, which find broad popularity in scientific, biomedical, and also, more recently, in industrial applications.

Short and ultrashort pulses generated by lasers have durations from few tens of picoseconds (10^{-12} s) to well below femtoseconds (10^{-15} s). Laser media that allow such a short pulses need to have wide spectral bandwidths to sustain their generation, since, according to Fourier relation, $\Delta\omega\tau_p \approx 2\pi$. The gain bandwidth is usually a fraction of the available spectral bandwidth $\Delta\omega_g$. For example, the full bandwidth of the Nd:YAG allows pulses of ≈ 5 ps, while for many other solid-state laser materials they can definitely be well below that.

The technique that allows to achieve this performance is named "Mode-Locking," and can be implemented either passively, exploiting the saturable absorption properties of some nonlinear materials, or actively, by the use of externally driven acousto-optic or electro-optic (loss or phase) modulators.

For example, it has been shown that most of the fluorescence (or spectral) bandwidth is readily exploited by passive mode-locking. In such conditions the generated pulses are almost Fourier-limited, with duration $\tau_p \approx 2\pi/\Delta\omega_g$, and with a number of longitudinal modes locked in phase $N \approx \Delta\omega_g/(\pi c/L') = \Delta\omega_g T_R/2\pi = T_R/\tau_p$, where L' is the optical length of the cavity and T_R is the round-trip time.

At the beginning of the mode-locking process, only a few of these longitudinal modes experience a net gain above threshold, and they tend to oscillate uncorrelated in laser free-running operation. At this initial stage, the output intensity has a noisy pattern. It is only when the modes are forced by the modulating device to maintain a fixed phase relationship to each other that the output as a function of time can vary in a well-defined manner. Under these conditions, the laser switches to the mode-locking regime.

Thus, mode-locking corresponds to correlating the spectral amplitudes and phases, so that the initial randomness is removed and a localized radiation pattern emerges, that circulates in the laser cavity with a repetition-rate of one per round-trip. This appears at the output as a pulse train, that can be continuous or a modulated bunch, depending on the pumping modalities. The conditions for obtaining stable mode-locking operation and well-formed ultrashort pulses are not trivial, and are reviewed in detail by Keller (2003).

For the purpose of illustrating the principle, continuously pumped active mode-locking is presented based on a time-domain model essentially due to Haus (1984), which is able to capture the main features of laser mode-locking. The model is not concerned with the starting mechanism itself, and assumes an already formed light pulse traveling inside the cavity. Looking for the conditions of self-reproducibility, let the field be

$$\vec{E} = \hat{e}E(t), \quad (62)$$

with

$$E(t) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} A(\omega) e^{-i\omega t} d\omega. \quad (63)$$

$E(t)$ and $A(\omega)$ are Fourier transforms of each other, representing pulse envelopes in their domains at some position into the cavity.

Assuming a linear laser cavity of length L , containing a gain medium of length ℓ and a gain coefficient with a frequency dependence $g(\omega) = g_0/[1 + (\omega - \omega_0)^2/\Delta\omega_g^2]$, where (in this case) g_0 is the saturated gain coefficient at the center frequency ω_0 of the gain medium, after one passage in the gain medium $A(\omega)$ becomes $\exp\{g_0\ell/[1 + (\omega - \omega_0)^2/\Delta\omega_g^2]\}A(\omega)$.

The unavoidable cavity losses (either passive or due to output coupling) can be modeled introducing a loss coefficient per unit length, so that the overall losses can be thought of as $\alpha_i L_i$, with L_i an appropriate loss medium length. A passage through it produces the change $\exp(-\alpha_i L_i)A(\omega)$.

Finally, the essential element in the mode-locked laser is the modulator, for example, an active, externally driven acousto-optic device of loss coefficient α_m and length L_m , producing a time dependent loss $\alpha_m L_m[1 - \cos(\omega_m t)]$ at the modulation frequency ω_m . This is best described in the time domain, affecting directly the field envelope after a passage through it: $\exp\{\alpha_m L_m[1 - \cos(\omega_m t)]\}E(t)$.

By taking the appropriate Fourier transforms to describe all the actions in the time domain, and assuming low net gain as well as low losses so that only first order terms in their expanded expressions are kept, after one round-trip time T_R , at the same space position we have:

$$E(t + T_R) = \left[1 + 2g_0\ell \left(1 + \frac{1}{\Delta\omega_g^2} \frac{d^2}{dt^2} \right) - 2\alpha_i L_i - 2\alpha_m L_m (1 - \cos(\omega_m t)) \right] E(t). \quad (64)$$

Steady-state operation requires self-reproducibility, $E(t + T_R) = E(t)$, and for this to happen it needs

$$\omega_m = \frac{2\pi}{T_R}.$$

Since the pulse tends to adjust itself for minimum losses, the modulation function can be expanded up to its first nonzero contributed term, getting the final form of the mode-locking equation:

$$\left[\frac{d^2}{dt^2} - \frac{\alpha_m L_m \omega_m^2 \Delta\omega_g^2}{2g_0\ell} t^2 + \Delta\omega_g^2 \left(1 - \frac{\alpha_i L_i}{g_0\ell} \right) \right] E(t) = 0. \quad (65)$$

This is written in a way that evidences its similarity with the Schroedinger equation of one-dimensional harmonic oscillator:

$$\left[\frac{d^2}{dx^2} - \frac{m^2 \omega^2}{\hbar^2} x^2 + \frac{2mE}{\hbar^2} \right] \psi(x) = 0. \quad (66)$$

As for (66), equation (65) has Hermite-Gauss solutions of integer order n :

$$E_n(t) = H_n(2\pi t/\tau_p) \exp \left[-(2\pi t/\tau_p)^2/2 \right]. \quad (67)$$

with

$$\begin{aligned} \frac{2\pi}{\tau_p} &= \left(\frac{\alpha_m L_m \omega_m^2 \Delta\omega_g^2}{2g_0\ell} \right)^{1/4} \\ \left(1 - \frac{\alpha_i L_i}{g_0\ell} \right) &= (2n + 1) \left(\frac{2\pi}{\tau_p \Delta\omega_g} \right)^2. \end{aligned} \quad (68)$$

Since as a rule the gain barely exceeds the loss ($g_0\ell/\alpha_i L_i \approx 1$), the last relation in (68) can be put into a more transparent form as follows:

$$\begin{aligned} \frac{g_0\ell}{\alpha_i L_i} \left(1 - \frac{\alpha_i L_i}{g_0\ell} \right) &= \left(\frac{g_0\ell - \alpha_i L_i}{\alpha_i L_i} \right) \\ &= (2n + 1) \left(\frac{2\pi}{\tau_p \Delta\omega_g} \right)^2 \frac{g_0\ell}{\alpha_i L_i} \\ &\approx (2n + 1) \left(\frac{2\pi}{\tau_p \Delta\omega_g} \right)^2 \end{aligned} \quad (69)$$

which represents the excess gain over the threshold gain for continuous operation, needed to sustain a mode-locked Hermite-Gauss pulse of order n . Higher orders need more gain.

Fig. 11 Gain and losses in an actively mode-locked laser, and its generated pulse train. The dotted line sets the net gain of the laser for continuous operation, and the extra, modulated loss are shown in full line above it. With periodicity of a round-trip time, a temporal window is opened in which the net gain is positive, and the pulses can go through, as shown in full line at the bottom. Pulse duration not to scale with round-trip time in the figure.

Gain saturation leads to the stability of lowest order Gaussian pulse, and to instability of higher order solutions. If just the right net gain to excite the fundamental ($n = 0$) solution is supplied, higher order ones do not have enough gain to start. If the supplied gain is in excess to this amount so that higher order solutions can also start, the amplitude of the lowest order grows faster to the point that it saturates the gain which settles to its steady-state value, switching off the higher order solutions.

It is thus seen from (67) that the pulse is Gaussian in shape; furthermore from the first of (68) it is seen that the pulsewidth has a power dependence on both the modulation depth and the gain bandwidth. Fig. 11 illustrates qualitatively the interplay of gain and losses in an actively mode-locked laser, and its Gaussian envelope pulses.

Actually, passive mode-locking is definitely more used in practice, owing to its superior performance and simplicity, since reliable fast saturable absorbers exist for a wide range of lasers (solid-state, semiconductors and fibers) (Keller 2003).

“Fast” means that the absorber is supposed to recover its initial, unperturbed state, in much less than one round-trip time T_R . Kerr-lens mode-locking is based on optical Kerr effect, which modifies the refractive index nearly instantaneously with respect to the pulse envelope (typical electronic response $\sim 10^{-15}$ s): this affects the spatial focusing/defocusing of the intra-cavity beam which, in combination with an aperture provides the necessary loss modulation for many solid-state femtosecond lasers. Another application of the third-order “fast” nonlinearity, ubiquitous to all transparent materials, is the nonlinear polarization rotation, which is most often employed in ultrafast fiber lasers.

The most popular mode-locking concept today is certainly the SESAM (semiconductor saturable absorber mirror), used for a variety of lasers, wavelengths and pulse durations (from picoseconds to few femtoseconds). Its detailed design may vary according to the desired performance, however the general principle is based on semiconductor engineering of quantum well absorbers fabricated at low temperature, such that the lifetime of the excited carriers is squeezed from the nanoseconds to the picoseconds, and the saturable modulation loss can be precisely tuned within the range from $\sim 1\%$ to few tens %.

Passive mode-locking allows to exploit nearly all the available net gain bandwidth, producing pulses of few picoseconds in relatively narrowband solid-state materials such as Nd-doped crystals: $\tau_p \sim 1/\Delta\omega_g$. Active mode-locking produces instead longer pulses, due to the mild and broad time-window of the sinusoidal modulation compared to the fast, self-adaptive modulation window which compresses pulses more effectively, until a balance with bandwidth narrowing in the amplifier is achieved.

An important condition ensuring stability of continuous-wave-pumped picosecond mode-locking against spontaneous Q-switching requires that the intracavity circulating pulse energy be $E_c > \sqrt{E_{sat,A}E_{sat,L}Q_0}$, given the saturation energies of the absorber and of the laser material, and the round-trip modulation loss $\sim$ few %. Such instabilities cannot be excluded in principle, since typically $E_{sat,A} \ll E_{sat,L}$. The stability condition basically requires that the absorber be fully saturated at each round-trip, leaving no room for a slow growth of self-Q-switching over many round-trips.

In femtosecond lasers, dispersive effects and self-phase modulation cannot be neglected, however the main results for passive mode-locking still apply:

- full gain bandwidth exploitation possible, provided the laser design is carefully optimized
- possible instabilities are suppressed if the circulating energy exceed a certain threshold

Such threshold is small compared to the case of no dispersion (picosecond domain), since an intrinsic passive feedback helps stabilize the pulse energy: as the pulse energy starts to grow due to gain fluctuations, for example, self-phase modulation would broaden the pulse spectrum thus reducing the gain due to finite gain bandwidth.

Spectral broadening via self-phase modulation is more effective in femtosecond rather than picosecond lasers, since it is proportional to (peak power)/(pulse duration). Peak power is generally limited by optical damaging practical considerations, therefore shorter pulses can produce much broader spectra.

Conclusion

Since the discovery of laser action in ruby in 1960, a broad variety of lasers has been demonstrated over the years, with many of them finding important practical applications that overall cover a very large portion of the electromagnetic spectrum from X-rays to the THz.

Laser light can be manipulated to enhance its spectral and spatial coherence properties: the invention of unstable resonators (Siegman 1986) has made possible high-power diffraction-limited lasers, while sophisticated electronically-stabilized ultra-narrow bandwidth lasers have become essential tools in many exciting applications, such as gravitational wave detection. Furthermore, even the quantum nature of laser light is presently being exploited for practical applications such as cryptography and next-generation quantum computing.

In this Chapter we have presented the basic principles and the most important operating regimes and properties of lasers. These represent the basis for a more advanced investigation and further exploitation of technical tools and methods in laser design and modeling.

It should be remarked that, along with laser physics and technology, nonlinear optics rapidly evolved, for obvious reasons: besides the interest in the rich variety of theoretical aspects that can be tested also experimentally for the first time due to the very unique properties of the laser light, nonlinear optical effects, such as harmonic generation, wave mixing, stimulated scatterings, self-focusing and so on, have evolved into many technologically important applications. In particular, due to their very nature, fiber lasers display and take advantage of an epiphany of nonlinear optical effects.

Abstract

Electron accelerators such as synchrotrons and storage rings are the best sources of X-rays and ultraviolet photons for research and technological applications. The physical mechanisms for all these sources use relativistic effects to increase the emission and its photon energies, and require an electron (or positron) beam moving at relativistic speed. The specific implementation of this strategy is reviewed here for different types of synchrotron or synchrotron-related sources: bending magnets, wigglers, undulators, helical wigglers, and free-electron lasers (FELs).

Introduction: X-ray sources

X-rays and ultraviolet photons are very extensively used not only for medical applications but also in research and technology. They are the basic ingredients of a wide variety of techniques ranging from microscopy and spectroscopy to imaging and structural analysis. The reason for their broad usefulness is quite fundamental: they possess photon energies and wavelengths that match basic magnitudes such as the binding energy of valence or core electrons and the length of chemical bonds.

As a consequence, the development of powerful X-ray and ultraviolet sources has been for many decades a high priority for research in many different disciplines. Progress in this field, however, has been rather slow until the advent in the late 1960s of the sources in the class broadly labeled as “synchrotrons.”

A conventional, non-synchrotron source emits X-rays or ultraviolet photons by bringing electrons to an excited state and then exploiting their radiative decay. Considering the photon energies to be emitted, the process must involve core electrons. Its effectiveness is limited: for example, pumping core electrons to an excited state requires putting a high power in the system (e.g., by bombarding it with electrons)—but the power is limited by the possible thermal damage to medium.

Furthermore, the photon emission occurs over a broad angular range. This limits the collimation of the source and its usefulness in experiments that require not only a high photon flux but also a high intensity and/or a high coherence.

The best parameter to characterize the source quality is the so-called brightness or brilliance, b . Roughly speaking (Fig. 1), this parameter is proportional to the flux F and inversely proportional to the source area A and to the (solid) angular range of emission Ω :

$$b = \text{constant} \times F / (A\Omega) \quad (1)$$

(more precisely, F is the number of photons per second emitted in a given bandwidth of 0.1%; A is the product of the horizontal and vertical source sizes; Ω is the product of the horizontal and vertical angular spreads of the emitted photon beam).

A limited flux and a large angular range result in a small brightness. Limited brightness was a major problem in the experimental use of X-rays and ultraviolet photons until the advent of synchrotrons. For example, with a synchrotron source of today certain crystallographic experiments take a few minutes, whereas before they required days or months or were impossible.

For visible light, high brightness is obtained from lasers. This is not easy for X-rays: as discussed later, the effectiveness of the lasing mechanisms decreases and the fabrication of optical cavities is problematic. Only in recent years high-peak-brightness X-ray free electron lasers have been realized, triggering a new revolution.

[☆]Change History: September 2022. G Margaritondo updated all sections. All figures were redrawn and therefore updated.

Fig. 1 The brightness b is the parameter which is most often used to characterize the quality of photon sources, including synchrotron sources.

Fig. 2 The emission of photons by an electron during its cyclotron motion is a good starting point to analyze the mechanism of synchrotron sources. The analysis, however, must be performed for a motion at relativistic speed, $v \approx c$.

Before the advent of FELs, the X-ray sources in the broad “synchrotron” class had solved the problem of increasing the flux and the brightness with a radically different approach with respect to the classical sources (that still dominate medical applications). This strategy was based on a clever use of relativistic effects and required the electrons or positrons moving at a speed close to the speed of light, c . The light mass of such particles made them easier to accelerate and therefore more effective in emitting X-rays than heavier particles such as protons.

The relativistic basis of synchrotron sources

Consider (Fig. 2) a very simple emitter of electromagnetic waves: an electron moving along a circular orbit under the action of a constant magnetic B -field (cyclotron motion). The emitted photon energy $h\nu$ is determined by the cyclotron frequency, which in classical physics is given by $\nu = eB/(2\pi m_o)$, where e and m_o are the charge and the rest mass of the electron. This result derives, as it is well known, from the balance between the Lorentz force and the mass multiplied by the centripetal acceleration. The typical emitted photons have rather low energies with respect to X-rays.

Imagine, however, the same phenomenon when the speed v of the circulating electron becomes close to the speed of light. In an inertial reference frame moving with the same velocity as the electron at a given time (hereafter called the “electron frame”), the transverse Lorentz force $e\nu B$ of the B -field becomes a transverse electrostatic force of magnitude $\gamma e\nu B$, where the relativistic γ -factor (the energy of the moving electron divided by $m_o c^2$) is:

$$\gamma = (1 - (v^2/c^2))^{-1/2}. \quad (2)$$

As a consequence, relativistic dynamics predicts a cyclotron frequency $\gamma eB/(2\pi m_o)$, which is γ times larger than the aforementioned classical result. The emitted photon energy in the electron reference frame is also multiplied by this factor, shifting toward the ultraviolet and X-ray spectral domains.

This shift toward shorter wavelengths and larger photon energies is further enhanced if one observes the emission in the reference frame of the laboratory. Imagine, for example, that the emitted photon energy is measured in the laboratory frame along the direction of the electron velocity. Since the source (the electron) is in motion, the photon energy is affected by the Doppler effect, which for electromagnetic waves is a relativistic phenomenon.

In the “forward” direction of the electron (source) velocity, the Doppler effect multiplies the photon energy by a factor $[(1 + v/c)/(1 - v/c)]^{1/2} = \gamma (1 + v/c)$. In the extreme relativistic case $v^2/c^2 \approx 1$, this factor is close to 2γ . Overall, therefore, relativity increases the classical emitted photon energy for the cyclotron motion by a factor $\approx \gamma(2\gamma) = 2\gamma^2$.

The mechanism just described is active in the photon emission by “bending magnets” (Fig. 3). These are the dipole magnets that keep the electrons circulating in a closed orbit within the vacuum chamber of an accelerator such as a storage ring. The deflection of the electron trajectory causes a (centripetal) acceleration and therefore the emission of electromagnetic waves. The mechanism is roughly equivalent to that of a portion of a cyclotron trajectory orbit, and the characteristics of the emission are also similar although a rigorous description requires a more sophisticated electrodynamics treatment.

In the first approximation, in fact, the center of the photon energy spectrum emitted by a bending magnet is close to $2\gamma^2$ multiplied by the classical photon energy given by the cyclotron frequency, $h\nu = heB/(2\pi m_o)$. For a typical B -field of 1T, the

Fig. 3 (Dipole) bending magnets are used to keep electrons (grouped in bunches) circulating along closed orbits in the vacuum chamber of a storage ring (top view).

Fig. 4 (A) The emission of photons by an electron, whose trajectory is deviated by a bending magnet, occurs over a wide angular range in the electron reference frame. Relativity drastically reduces this angular range when the emission is observed in the laboratory frame. (B) In practice, however, the angular collimation is only present for the vertical direction. In the horizontal direction, electrons at different points of the orbits emit in different directions and the horizontal angular range is set by the portion of the orbit “seen” by the detector.

classical photon energy would be $\approx 4 \times 10^{-23}$ J or ≈ 0.2 meV, well below the ultraviolet and X-ray range. If one takes a typical electron energy of 1 GeV in a storage ring, the γ -value is $\approx 2 \times 10^3$, the factor $2\gamma^2$ is $\approx 4 \times 10^6$, and the relativistic emission becomes $\approx 2 \times 10^2$ eV, which falls indeed in the X-ray range.

As discussed later, all types of synchrotron sources exploit this combination of relativistic effects to shift their emission into the ultraviolet and X-ray ranges. In addition to the spectral shift, relativity has other beneficial effect: a shrinkage of the angular spread of the emission and a corresponding increase in the brightness.

This angular-range shrinkage can be easily understood. As shown in Fig. 4A, a photon emitted in the vertical plane, when observed from the reference frame of the emitting electron, can travel in a direction quite far from that of the electron velocity (the “forward” direction). When seen from the laboratory frame, the photon direction changes becoming very close to the same “forward” direction.

The reason is that the relativistic Lorentz transformations include a γ -factor for the “forward” direction coordinate, whereas the transverse direction coordinates are invariant. When calculating the angle between the photon direction and the “forward” direction as the ratio of the two velocity components, the γ -factor appears in the denominator but not in the numerator. This confines the emission within an angular range $\approx 1/\gamma$ from the “forward” direction. Because of the large value of γ , this relativistic effect strongly collimates the emission, enhancing the brightness.

Note, however, that for bending magnets the angular collimation is only present in the vertical direction. In the horizontal direction (Fig. 4B), the angular range depends on the portion of the electron orbit “seen” by the detector.

Finally, it should be noted that the brightness (Eq. 1) is also enhanced because relativity boosts the emitted power. Electrodynamics shows that the power emitted by an accelerated charge is proportional to the square of the acceleration. The relativistic transformation of the transverse acceleration includes a factor γ^2 , which becomes γ^4 for the square of the acceleration and for the emitted power. Thus, large γ -values boost the emitted power.

Main properties of synchrotron sources

Based on the above discussion, we can summarize the main properties of bending magnets and other synchrotron sources as follows:

- **Spectral domain:** centered in the ultraviolet and X-ray region because of the relativistic factor $\approx 2\gamma^2$ in the emitted photon energies.
- **Bandwidth:** a bending magnet emits over a wide photon energy range. The reason can be understood by considering an emitting electron as it passes through the bending magnet. Due to the angular collimation of the emission, the electron can be imagined as a torchlight with a very narrow beam. A detector (Fig. 5A) is illuminated by this “torchlight” for a very short time. The corresponding bandwidths of frequencies and photon energies (according to the Fourier theorem and/or to the uncertainty principle) are inversely proportional to the illumination time and therefore quite broad. A detailed theory shows that for a bending magnet the photon energy bandwidth is close to the relativistic “cyclotron” photon energy $\approx 2\gamma^2\hbar eB/(2\pi m_0)$ so that the relative bandwidth $\Delta h\nu/(h\nu) \approx 1$. Overall, the emitted spectrum of a bending magnet can be roughly imagined as a broad peak with center close to $\approx 2\gamma^2\hbar eB/(2\pi m_0)$ and $\Delta h\nu/(h\nu) \approx 1$. In some other types of synchrotron sources such as the undulators (see Fig. 5B and the discussion later), the bandwidth is narrow rather than broad as in bending magnets. As shown in Fig. 6, a log–log plot of this peak gives the familiar synchrotron spectrum.
- **Collimation:** the vertical emission is limited to an angular range $\approx 1/\gamma$.
- **Flux:** high and proportional to γ^4 .
- **Brightness:** very high because of the high flux and strong collimation. In addition, the brightness is also enhanced by the small source area A (Eq. 1). The effective A is determined by the transverse section of the electron beam circulating in the accelerator. In modern storage rings as well as in other accelerators, the trajectories of the electrons are controlled with extreme accuracy. This strongly limits A boosting the brightness.
- **Coherence:** the lateral coherence of a source of electromagnetic radiation increases as the product of the source size times the angular range decreases, until it reaches the “diffraction limit” (for which the product roughly equals the wavelength). Thus, the same geometric factors that influence the brightness (Eq. 1) also determine the lateral coherence. For a bending magnet, the high angular collimation in the vertical direction produces high lateral coherence in the same direction. The longitudinal coherence is determined by the relative bandwidth $\Delta h\nu/(h\nu)$ and, for a bending magnet, it is quite limited. However, the longitudinal coherence can be increased by reducing the bandwidth with a monochromator.
- **Polarization:** for a bending magnet, the limited angular range confines the emission to directions close to the (horizontal) plane of the storage ring. From the corresponding viewpoints, the emitting electrons (Fig. 7, right) appear to move along a horizontal line, and their emission is linearly polarized with the photon electric field in the horizontal plane. Slightly out of the plane (Fig. 7, middle), the observed electron motion appears to follow an elliptical curve and the emitted light possesses a circularly polarized component. As discussed later, other synchrotron sources are also linearly or elliptically polarized.

Fig. 5 (A) An electron going through a bending magnet emits photons that illuminate the detector only during a short time pulse. This corresponds to a broad photon energy bandwidth. (B) An electron passing through an undulator, instead, illuminates the detector continuously producing a longer pulse and a narrower bandwidth. The undulator bandwidth is further decreased by other factors.

Fig. 6 In first approximation, the spectrum emitted by a bending magnet can be imagined as a broad peak. The conventional way to show the spectrum, however, is a log–log plot that transforms a peak-like line shape into the familiar spectrum of bending-magnet synchrotron sources.

Fig. 7 The polarization of the bending magnet emission can be understood by considering how electrons moving in a storage ring appear from different points of view. For example, in the ring plane (side view) the motion appears linear and the emission is linearly polarized.

- *Time structure:* The electrons circulate around a storage ring grouped in bunches. Every time a bunch passes through a source point such as a bending magnet, a pulse of photons is emitted. Thus, the time structure of a synchrotron source consists of short pulses separated by longer “dark” intervals. The parameters of the time structure depend on those of the storage ring, and the pulse duration can reach in some cases the picosecond range.

Different types of synchrotron sources

The previous discussion primarily dealt with bending magnet sources. Other types of synchrotron sources exist and are briefly reviewed here.

Wigglers

A wiggler (Fig. 8) is a periodic sequence of dipole magnets inserted in an otherwise straight portion of a storage ring. It produces a series of transverse “wiggles” in the electron path, each roughly equivalent to a portion of the trajectory in a bending magnet. Thus, the emission approximately corresponds to that of a series of bending magnets.

The positive aspects of a wiggler with respect to a bending magnet are mainly two. First, the flux and the brightness are multiplied with respect to a single bending magnet by the number of wigglers. Second, the B -field strength can be selected to tune the emission spectrum to a desired value (e.g., to very high photon energies in the hard-X-ray range). This is not possible for bending magnets since their field strength is dictated by the task of keeping the electrons in a closed trajectory around the ring.

Undulators

An undulator is a device similar to a wiggler except that the B -field strength is weaker and the “wiggles” along the electron trajectory are less pronounced. As a consequence, the emission properties are quite different from those of wigglers or bending magnets.

Roughly speaking, the “wiggles” in this case produce angular deviations smaller than $1/\gamma$ with respect to the axis of the undulator. Since the angular spread of the emission is $\approx 1/\gamma$, the emission corresponding to one “wigggle” illuminates the subsequent wigglers, producing coherent interference. As a result, the emitted peak intensity increases with the square of the number of wigglers rather than being proportional to it.

The photon energy spectrum of an undulator is also quite different from that of a wiggler or a bending magnet. First, the bandwidth is much narrower. The reason (Fig. 5B) is that for weak wigglers the detector is illuminated during the entire passage of the electron-torchlight through the undulator. The resulting long pulse corresponds to a narrow photon energy bandwidth. This effect is further enhanced by other factors. In essence, therefore, an undulator concentrates the emitted flux into a narrow bandwidth, achieving very high brightness.

This narrow bandwidth is centered at a photon energy which is determined by the undulator period (see Fig. 9). The physical explanation is rather simple: in the reference frame of an electron moving at relativistic speed through the undulator, the periodic transverse B -field is observed as the combination of a periodic transverse B -field plus a transverse periodic electric field perpendicular to the B -field, both moving at a speed $\approx c$. In other words, it appears as an electromagnetic wave.

Fig. 8 A wiggler is a periodic series of magnets inserted along a straight section of the storage ring. The magnets cause lateral undulations or “wiggles” of the electrons with respect to their otherwise straight trajectory. The resulting photon emission is similar to that of a series of bending magnets.

Fig. 9 Schematic explanation of how the two relativistic effects (Lorentz contraction of the undulator period and Doppler shift) determine the “central” emitted wavelength and photon energy of an undulator.

The electron backscatters this “wave”: this is the mechanism of synchrotron radiation emission. What is the wavelength of the backscattered wave? Obviously, it is related to the undulator period, L . However, in its reference frame the electron “sees” L shortened by a factor γ because of the relativistic “Lorentz contraction.” When observed in the laboratory frame, the wavelength is further decreased by a factor $\approx 2\gamma$ by the Doppler effect, becoming $\approx L/(2\gamma^2)$. The corresponding photon energy is $\approx 2\gamma^2 hc/L$.

In addition to this photon energy, the undulator also emits higher harmonics corresponding to its integer multiples. As the B -field increases, the sequence of higher harmonic merges into one broad spectrum corresponding to the wiggler emission.

The fundamental-harmonic photon energy $\approx 2\gamma^2 hc/L$ of an undulator is shifted when the emission is detected along a direction other than the undulator axis, or when the B -field changes. The reason is similar in both cases: at an angle θ from the “forward” direction, the Doppler factor is no longer $\approx 2\gamma$ and becomes a function of θ . Similarly, as the B -field increases the transverse wiggles decrease the electron speed along the undulator axis and effectively modify the γ -factor in the Doppler shift.

Taking both effects into account, the first harmonic photon energy of the undulator changes from $2\gamma^2 hc/L$ to.

$$h\nu \approx (2\gamma^2 hc/L) / (1 + K^2/2 + \gamma^2 \theta^2), \quad (3)$$

where the K -factor is proportional to B . Eq. (3) has a very important impact on the operation of undulator sources: by changing the B -field (e.g., the gap between permanent magnets), one can tune the emitted photon energy to a desired value.

Contrary to bending magnets, undulators achieve high angular collimation not only on the vertical direction but also horizontally. In fact, during the entire emission process, the electron stays in a straight trajectory except for small transverse wiggles, and this limits the horizontal angular divergence. This also implies that the lateral coherence is high both vertically and horizontally.

Finally, the undulator emission is linearly polarized with the electric vector in the horizontal plane. The reason is that, when observed from the point of view of the detector, an emitting electron looks like an oscillating charge along a horizontal line.

Helical wigglers

For many applications of synchrotron sources, it is necessary to have elliptical polarization. Such a polarization does exist (Fig. 7) in the out-of-plane emission of bending magnets. However, the emitted intensity strongly decreases as the direction diverges from the horizontal plane. Therefore, bending magnets can only provide elliptically polarized radiation of weak intensity.

Dedicated sources for elliptical polarization are based on special magnet arrays that force the electrons to move along a periodic helical path rather than simply undulating in the transverse direction. Such devices can operate either in the wiggler mode (“helical wigglers”) or as undulators.

Free-electron lasers

Standard synchrotron sources are not based on lasers mechanism: they do possess laser-like properties such as high collimation, brightness, and coherence, but they are not lasers. Indeed, their emission mechanism is not based on optical amplification by stimulated emission as for a conventional laser.

There exists, however, a special class of synchrotron-related sources that operate with optical amplification, even though they are not based on stimulated emission: the free-electron lasers (FELs). They operate either as emitters of infrared radiation or as very powerful X-ray sources.

The realization of X-ray lasers is complicated also because optical cavities, which are standard components of conventional lasers, are not available. Formed by two reflecting or partially reflecting surfaces, the cavity increases the path of photons and the effects of optical amplification. However, reflection is very weak for X-rays, so lasing must be achieved without an optical cavity and requires strong optical amplification.

Fig. 10 Top: The main components of a FEL are a LINAC and a very long undulator. We see here a relativistic electron bunch produced by the LINAC entering the undulator and emitting a wave, which then travels with the bunch interacting with it. This interaction reshapes the bunch creating periodic “slices.” Bottom: The slice periodicity coincides with the wavelength, so the electrons in the slices emit waves in a coordinated fashion, causing optical amplification.

The basic ingredients of an FEL for X-rays are a linear electron accelerator (LINAC) and a very long undulator. The LINAC produces electron bunches of high energy. When a bunch enters the undulator, it starts emitting waves that then travel with the bunch. The electrons and the wave interact reshaping the bunch.

Note that the interaction disappears at the wave nodes, so the reshaping must produce a periodic structure. One can demonstrate that this structure consists of very thin “slices” with period equal to the wavelength. As seen in Fig. 10, electrons in these slices emit in a coordinated fashion, and this causes the optical amplification.

Although conceptually simple, this mechanism is very difficult to implement for short-wavelength X-rays. This is why X-ray FELs were realized only five decades after those for infrared radiation. And it also explains why an ordinary undulator or wiggler in a synchrotron source does not act as an FEL.

Several FELs for X-rays are now in operation in different countries, producing very exciting results. One important property of these sources is the time structure, consisting of pulses with duration determined by the passage of each electron bunch. The time scale is in the femtosecond range or even shorter, opening the door to the analysis of many important fast phenomena.

One should note, however, that FELs for X-rays cannot replace synchrotron sources based on storage rings. In fact, their very high peak brightness and ultrashort pulses, although suitable for specific applications, are not useful when longer pulses or a quasi-constant emission are required.

The overall picture

The different types of synchrotron or synchrotron-related sources, either already implemented or under development, provide extreme flexibility in matching the needs of a wide variety of applications. Fig. 11 is a summary overview of the characteristics of the emission of the main different machines.

Practical use of synchrotron sources

Synchrotron sources ceased long ago to be exotic instruments only used by a tiny minority of physicists. They have become instead standard instruments used by a large part of the research community in many diverse disciplines. Dozens of facilities are in operation in many countries, most of them at no cost for qualified users performing nonproprietary research. Additional programs often provide support to users for travel and lodging expenses.

Fig. 11 The main different types of synchrotron radiation sources.

Each synchrotron facility serves its users with a variety of instruments. Roughly speaking, the core of the facility is an accelerator such as a storage ring with its injection and control systems. The emitted photons are collected by beamlines that improve the photon beam characteristics (e.g., by selecting a narrow band of photon energies with suitable monochromators) and convey them to experimental chambers.

In the accelerator, the electrons must circulate under ultrahigh vacuum. Many of the beamlines are also under vacuum since no window can be used to separate them from the accelerator without sharply decreasing the photon beam intensity.

The typical operation cycle of a synchrotron facility begins with the injection of electrons (or positrons) in the accelerator. If this is a storage ring, the electron beam keeps circulating and emitting photons for hours or days as the energy lost through photon emission is restored by radiofrequency cavities. Natural losses steadily reduce the circulating electron beam until a new injection and the beginning of a new operation cycle. In many facilities, the injection is performed continuously so that the electron beam can circulate with no time limitations except for maintenance and equipment modifications.

Conclusion

Relativity enables high-energy electrons accelerated by magnetic devices to emit X-rays with exceptional properties: extreme flux, brightness and collimation, selected wavelengths, polarization, and coherence. The resulting synchrotron radiation sources constitute now a worldwide network of facilities with unprecedented magnitude in terms of instrumentation and user population. In recent years, new research opportunities were opened up by a variant of this class of X-ray emitters, the “free electron lasers,” with exceptional peak brightness and ultrashort pulses.

Abstract

Since their discovery in 1895, X-rays have become a vital tool to determine the chemical and atomic structure of materials. It is currently used in many fields, including biological systems and human beings. X-ray technology has tremendously evolved from the first commercial x-ray tube built by Carl Heinrich Florenz Müller in 1896 to the modern synchrotron sources, allowing increasingly precise and sophisticated analyses in hard and soft matter.

In this chapter, after brief notes on cosmic ray sources, the devices capable of producing X-rays from vacuum tubes up to modern particle accelerators for the production of Synchrotron Radiation (SR) and Free Electron Lasers (FEL) are described.

Key points

- **Astrophysics** is a science that employs the methods and principles of physics and chemistry in the study of astronomical objects and phenomena
- **Atomic particle** All matter consists of atoms that contain a nucleus and orbiting electrons
- **Bremsstrahlung** braking radiation; refers to any radiation produced by deceleration of a particle
- **Bending Magnet** Device used to bend the electron beam produced by an accelerator tube
- **CNT** Carbon Nano Tube
- **Laser Plasma** is a product of the very complicated process of laser-matter interaction
- **Synchrotron** is a particular type of cyclic particle accelerator
- **Undulator** is a device similar to a wiggler except that the B-field strength is more limited
- **Wiggler** is a series of magnets designed to periodically laterally deflect ('wiggle') a beam of charged particles
- **XFEL** Free Electron Laser sources that produce radiation with brightness several orders of magnitude higher than undulators on third-generation rings
- **X-ray** form of ionizing radiation
- **XRF** X-Ray Fluorescence is an analysis technique that can be applied to most inorganic materials

Introduction

X-rays are forms of ionizing radiations, i.e., they have enough energy to ionize atoms and molecules in matter, including the biological one represented by cells and tissues. They are electromagnetic radiations having a wavelength (λ) between 10 and 0.01 nm, frequency from about 3×10^{16} to 3×10^{19} Hz and having energy between 0.1 and 100 KeV.

"X-rays" was the name given by W. C. Roentgen to the highly penetrating rays that are produced when high-energy electrons strike a metal target. On November 8, 1895, he noted for the first time this phenomenon and on December 28, 1895, Roentgen

astonished the scientific world with his preliminary report “Ueber eine neue Art von Strahlen” (Roentgen, 1895) given to the president of the Wurzburg Physical-Medical Society (along with experimental radiographs and by the X-ray image of his wife’s hand). A few weeks later C.H.F. Muller was able to construct in his factory in Hamburg the first commercial X-ray tube for one of local hospitals. This was a milestone of what was become a major technical industry. Röntgen received the Nobel Prize in Physics in 1901 for this discovery. X-ray technology is one of the most important inventions of the nineteenth century. It plays a major role in our daily life. X-rays are nowadays one of the most powerful tools to investigate hard and soft matter.

There are numerous applications of X-rays in the various fields of science and medicine. In addition to radiography, in the medical field, applications for Computed Axial Tomography (ACT), Micro tomography are known. In biology and chemistry, X-rays are used for structural determination of both inorganic and biological molecules by X-ray diffraction from crystals (Giacovazzo, 2002). Baggage inspection is based on X-ray imaging in checkpoints of airports or sensitive areas, to control the structural integrity of aircrafts and transports or more generally, to inspect the insights of materials subjected to mechanical/thermal stress. In the food industry, X-ray are used to check for the presence of extraneous objects inside the packaging. In the field of Cultural Heritage to analyze paintings, archaeological finds, or to carry out elemental analyses in pigments or in metals using Fluorescence X (XRF). Of course, different types of radiation sources have been studied and developed for each application.

In nature, as it turned out later, there are sources of X-rays generated by cosmic processes or nuclear particles decay phenomena.

Natural sources (astronomy)

X-ray source, in astronomy, are cosmic objects that emit radiation at X-ray wavelength (Britannica, 2018). Since the Earth’s atmosphere absorbs X-rays from space, detectors and telescopes capable of measuring the weak emissions generated by celestial bodies have been launched into space (high above Earth’s atmosphere) The sun was the first celestial object for which radiations in the range of X-rays wavelengths were measured (1949). The radiations coming from the sun are substantially weak and it is notable only because its proximity to the Earth. Only 30 years later with the launch of the HEAO 2 satellite better known as the Einstein Observatory (Giacconi et al., 1979), more than 150 stars emitting X radiation were observed.

In Astronomy, X-rays come from material that has been heated to extreme temperatures by a small number of physical processes:

- (1) Accretion: material falls within the gravitational potential of a celestial body, potential energy is converted into kinetic energy, and via different processes (collisions, friction) into heat, and the heated material cools then by emitting X-rays. Common environments where accretion occurs are binary stars, in particular those containing “stellar remnants,” i.e., white dwarfs (Pravdo et al., 1986), neutron stars (Morton, 1964), and black holes (Wilkins et al., 2021). Because of their extreme densities, material is accelerated to 1000s of km/s (white dwarfs) to highly relativistic velocities (neutron stars, black holes), which then facilitates heating material to very high temperatures. However, also young (single) stars that are still in the process of formation accrete from a proto-stellar disc, and the most luminous X-ray sources are super-massive black holes (millions to billions of solar masses) in the centers of most (maybe all) galaxies, accreting interstellar dust/gas.

In terms of heating processes, there are two main branches:

- Shock-heating of material that is abruptly decelerated, e.g. in the case that it hits the stellar “surface” (=atmosphere), which is the case if the accreting star has a sufficiently strong magnetic field (young some white dwarfs, most neutron stars). Material cools via thermal bremsstrahlung.
- In the case of no/weak magnetic fields of the accreting object, an accretion disk (flat structure) forms, material drifts inwards, angular momentum is transported outwards, and gravitational energy is gradually converted into heat via friction. Temperatures in the inner discs around white dwarfs, neutron stars, and black holes reach temperatures where they emit X-rays (again, material simply cools, and emits thermal bremsstrahlung).

So the process of generating the X-rays in these systems is fairly general, and does not depend too much on the detailed properties of the accreting object.

- (2) High-energy processes within the outer layers of stars, generally called “stellar activity,” such as e.g. in the sunspots. These are related to magnetic phenomena (twisted field lines, magnetic reconnection). As such, the Sun is an X-ray source—and some other stars are much more active and X-ray luminous.

Conventional sources

X-ray tube

Whenever a charged particle is accelerated or decelerated, it emits energy in the form of photons. This process takes place within an X-ray tube to create X-rays. At one end of the tube is the source of electrons or the cathode and at the other end of the tube is the metal target, or anode. To produce X-rays, electrons are accelerated from the cathode to the anode with a high voltage. When the electrons hit the anode, they are quickly stopped. This rapid change in speed causes the emission of X-ray photons. These X-rays are commonly called bremsstrahlung or “braking radiation.”

Bremsstrahlung is the German word for slowing down or braking. Bremsstrahlung is an electromagnetic radiation produced by the deceleration of a charged particle, deflected by another charged particle, typically an electron by the atomic nucleus. Assuming

Fig. 1 Radiation produced by an electron passing through an atom and being deflected by the nucleus.

that there are charged particles in a piece of matter and that a high-speed electron passes close to it, the trajectory of the latter will be deflected due to the electric field around the atomic nucleus, as shown in the image (Fig. 1).

The moving particle, when deflected, loses kinetic energy and, to satisfy the energy conservation principle, emits radiation in the form of a photon; bremsstrahlung radiation is characterized by a continuous distribution of radiation that becomes more intense (and moves towards higher frequencies) with the increase in the energy of the bombarding electrons (braked particles).

An electron that completely avoids the orbital electrons on passing through an atom of the target may travel sufficiently close to the nucleus of the atom to come under its influence. Since the electron is negatively charged and the nucleus is positively charged, there is an electrostatic force of attraction between them. As the electron approaches the nucleus, it is influenced by a nuclear force much stronger than the electrostatic attraction. As it passes by the nucleus, it is slowed down and deviated in its course, leaving with reduced kinetic energy in a different direction. This loss in kinetic energy reappears as an X-ray photon.

If all the energy carried by an electron is transformed into radiation, the energy of an X-ray photon is

$$E_{\max} = h\nu_{\max} = eV$$

Where h is the Planck's constant, $\nu_{\max}$ the photon frequency. The indication max indicates that this is the maximum possible energy, e is the charge of the electron and V the accelerating potential. If the frequency is substituted with the wavelength, the above expression becomes

$$h\nu_{\max} = hc/\lambda_{\min} = eV \quad \text{and} \quad \lambda_{\min} = hc/eV = 12398/V$$

The energy contained in each bremsstrahlung photon emitted from an X-ray tube extends from that associated with the peak electron energy all the way down to zero. In other words, when an X-ray tube is operated at 70 kVp, bremsstrahlung photons with energies ranging from 0 to 70 keV are emitted, creating a typical continuous X-ray emission spectrum. Since total conversion of the electron energy into radiation is not a highly probable event, the radiation of the highest intensity is obtained at a longer wavelength compared to $\lambda_{\min}$ (1.5 times). Fig. 2 shows some X-ray continuous spectra as a function of the accelerating voltage.

If the bombarding electrons have sufficient energy, they can knock an electron out of an inner shell of the target metal atoms. Then electrons from higher states drop down to fill the vacancy, emitting X-ray photons with precise energies determined by the electron energy levels. These X-rays are called characteristic X-rays. In summary, transitions of orbital electrons from outer to inner shells produce characteristic X-rays. Since the electron binding energy for every element is different, the characteristic X-rays produced by the various elements are also different. This type of X-radiation is called characteristic radiation because it is characteristic of the target element. The effective energy characteristic X-rays increases with increasing atomic number of the target element. The characteristic lines of this type of spectrum are called K, L and M and correspond to the transition from higher energy orbital to the K,L,M orbital. When the two orbital involved in the transition are adjacent then the line is called α , if they are separated by another shell the line is called β (Fig. 3).

For example, K electrons for tungsten anode have binding energies of 69.5 keV, and L electrons are bound by 12.1 keV. Therefore, the characteristic X-ray emitted has energy

$$69.5 - 12.1 = 57.4 \text{ keV}$$

Fig. 2 X-Ray radiation spectra as a function of accelerating voltage.

Fig. 3 Characteristic lines K_{α} and K_{β} of Cu spectra superimposed on the brehmsstrahlung.

Sealed tube and rotating anode sources

The X-ray tube is a large diode valve, which is designed to produce fast moving electrons and then cause the electrons to decelerate rapidly in a vacuum environment. A conventional generator consists of a high-voltage power supply electronically controlled applied between the anode and the cathode. In Fig. 4 the sketch of a sealed tube is showed.

It consists of a cathode with a filament that emits the electrons that are accelerated under vacuum by the high voltage. The electrons hit the anode and produce the characteristic X-ray spectrum relative to the metal of the anode. The high vacuum is necessary because the presence of gas molecule would decrease the efficiency of the tube. Normally this type of sources is highly inefficient because only 0.1% of power used is transformed into X-ray, the rest is dissipated as heat. In the rotating anode the anode has a cylindrical shape and to increase the efficiency of the X-ray beam the anode is continuously rotated. Thus, the electron beam

Fig. 4 Sketch of a sealed X-ray tube.

hits the metal of the anode in different positions permitting a better dissipation of heat. The increasing of the intensity of the beam may be quite an order of magnitude in respect to a sealed tube.

The intensity of a K line can be calculated using the equation:

$$I_K = Bi(V - V_K)^{1.5}$$

Where B is a constant, i the electrical current, and V_K the excitation potential of the K series. If the accelerating potential $V = 4V_K$ is applied the $K\alpha$ line is 90 times more intense than the white radiation of the equivalent wavelength (I_W). In this condition the ratio I_K/I_W is a maximum.

X-ray tube based on carbon nanotube field emitters

Over the last few decades, the technology for manufacturing X-ray sources has not substantially changed. Different types of generators have been developed according to the applications for which X-rays are used, i.e., in high definition medical diagnostics, safety inspection or high throughput industrial control processes (Parmee et al., 2015). The thermionic sources are limited due to the slow temporal response and the size and spatial amplitude of diffusion. For these reasons, new types of field emission X-ray sources have been studied.

In the tubes with Thermionic Emission (TE) the electrons are produced from a metallic filament, often consisting of Tungsten, which when crossed by an electric current heat it to a temperature above 1000 °C. Since the emission is strictly dependent on the temperature of the filament, as the temperature of the emitter increases the electrons able to overcome the surface barrier increase. In such tubes the filament current is controlled analogically. One of the disadvantages of this type of technology is the large production of heat that must generally be disposed of by cooling with the circulation of water or coolants. A second limitation consist in the slowness of the response when it is necessary to rapidly vary the intensity of the electron beam to increase or decrease the intensity of the X-ray beam. This slowness is due to the inertia in the heating or cooling of the filament.

Field Emissions (FE) offer several significant benefits. FE sources are often physically more compact than TE systems. The emission process occurs at room temperature and therefore does not require a heat sink. FE is a tunneling process and consequently provides almost instantaneous emission. The rise times are of the order of the microseconds as opposed to the TE that are of the order of milliseconds.

CNT-based emitters have several advantages over thermionic electron sources (Heo et al., 2012). The advantages are in the fact of having little heat generation compared to a thermionic tube, an important characteristic for creating small sources. They are simple to make and easily electronically controlled to generate pulses even of high frequency. Finally, they allow generating high current densities for electron and X-ray microscopy devices.

Synchrotron sources

Synchrotron radiation (SR) is emitted when charged particles moving with relativistic speeds are forced to follow curved trajectories in magnetic fields. The first visual observation of SR was in 1948 from the General Electric synchrotron in the USA during investigations into the design and construction of accelerators suitable for the production of very high-energy electrons. Over the next 50 years, an explosive growth in the building of accelerators optimized for SR production has turned this interesting radiative energy into a valuable research tool (Winik, 1995).

Whenever charged particles undergo an acceleration they emit electromagnetic radiation. An electron oscillating at radio-frequencies in an antenna emits radio waves. When electrons are subjected to an acceleration perpendicular to their velocity, for example when they pass through a magnetic field, their direction is changed and they begin to travel in a circular path. Charged particles moving under the influence of an accelerating field emit electromagnetic radiation. The energy of this radiation is dependent on the velocity of the particle. The total instantaneous power P emitted by an electron moving on a circular orbit is

$$P = \frac{2e^2 c E^4}{3R^2 (m_0 c^2)^4} = \frac{2e^2 c \gamma^4}{3R^2} \quad (1)$$

where P is the energy emitted per unit time, e is the particle charge, c the speed of light, E the energy of the particle, m_0 its mass at rest and R the bending radius of the orbit. The emitted radiation has very different characteristics in dependence of the velocity v of the particle. If $v \ll c$ the emitted pattern is identical to the well-known dipole radiation field (Fig. 5a). When the speed increases to almost light velocity the whole power is compressed into a narrow cone in forward direction tangentially to the orbit (Fig. 5b). The radiation emitted is called synchrotron radiation. The quantity γ in eqn. 1, which is the ratio of the total energy to the rest energy of the particle, is of considerable importance since it is related to the opening angle $\Delta\Psi$ of the cone of radiation in the perpendicular plane of the orbit by:

$$\Delta\Psi \cong 1/\gamma$$

where $\Delta\Psi$ is expressed in radians.

A storage ring synchrotron consist of an arrangements of devices where charged particles travel at essentially the speed of light in evacuated pipes under the influence of magnets which are positioned around a closed orbit (Winik, 1995). Acceleration is achieved by the application of radio frequency electric fields at RF cavities along the circumference of the ring. The magnetic fields grow synchronously with the acceleration in order to keep the particles on the constant radius path. Such accelerators can be used with protons or electrons, and even with heavier positive ions. The particles travel in the closed loop for periods of several hours while synchrotron radiation spread out from all curved parts of the orbit.

In general, three kinds of magnets are used to make the necessary magnetic fields: bending magnets, wigglers and undulators.

Bending magnets

In bending magnets, a simple dipole structure is used to constrain the electrons in a curved path. The radiation emitted is extremely intense and extends over a broad wavelength range from the infrared through the visible and ultraviolet, and into the soft and hard

Fig. 5 Emission pattern of radiation from centripetally accelerated electrons: (a) non relativistic case $v \ll c$. (b) relativistic case $v \cong c$.

X-ray regions of the electromagnetic spectrum. A typical output curve for a bending magnet source has a smooth spectral distribution with a broad maximum near the so-called critical wavelength. This critical wavelength depends on the square of the energy of the electrons and the bending radius in the dipole. In practical units of angstroms, it can be calculated as:

$$\lambda_c = 18.64 / (B \cdot E^2),$$

where B (the dipole field) is in Tesla and E (the ring energy) is in GeV. The critical wavelength (or energy) has the property that one-half of the power radiated is above this wavelength and one-half below.

Wigglers

High-field wiggler magnets are often used as sources in order to increase the flux at shorter wavelengths. We can best think of a wiggler as a sequence of bending magnets of alternating polarities which gives a $2N$ enhancement in the flux, where N is the number of poles (Fig. 6). Each magnet bends the electron beam through an angle large compared with mc^2/E . The properties of wiggler SR are thus very similar to that of dipole radiation with a reduction in the critical wavelength because of the higher field. For superconducting wiggler magnets a value of 6 Tesla, as opposed to around 1.2 Tesla for conventional dipoles, would be typical. The characteristics of the synchrotron radiation from the wiggler are the same one as from the bending magnet, and so, the critical energy play a determinant role. To reach the same spectral range as from the bending magnets the magnetic flux density within the wigglers must be the same as within the bending magnets, if the magnetic field in the wiggler is higher than the ring bending magnet field, the wiggler spectrum extend to higher photon energy. The photon flux as well as the central intensity of the radiation emitted by the wiggler is the same as from the bending magnet but more intensive by a factor N_p , where N_p is the number of poles within the wiggler.

Undulators

An undulator magnet is similar to a wiggler, in that it is also a succession of alternating magnetic poles (Fig. 7a). However, in this case the angle of bend in each pole is of the order of mc^2/E , so that the small angular divergence due to the emission pattern of synchrotron radiation is not significantly increased. The radiation emitted at the various poles interferes coherently resulting in the emission of a pencil-shaped beam (Fig. 7b) peaked in narrow energy bands at the harmonics of the fundamental energy. For N poles, the beam's opening angle decrease by a factor $N^{1/2}$ and thus the intensity per solid angle increases as N^2 .

Fig. 8 shows the performance in terms of brilliance of bending magnets, wigglers and undulators for a 6 GeV Energy synchrotron with a current in the ring of 100 mA.

Synchrotron radiation characteristically is highly polarized and continuous. Its intensity and frequency are directly related to the strength of the magnetic field and the energy of the charged particles affected by the field. Accordingly, the stronger the magnetic field and the higher the energy of the particles, the greater the intensity and frequency of the emitted radiation. The high intensity, broad spectral range and other properties such as collimation, polarization, pulsed-time structure, partial coherence, make synchrotron radiation a powerful tool for basic and applied studies in biology, chemistry, medicine, and physics, as well as in applications to technology such as X-ray lithography, micromechanics, materials characterization and analysis. Brilliance of

Fig. 7 (a) The arrangement of magnets within an undulator. (b) The characterization of the undulator radiation. L is the period length.

Fig. 8 Plot of Brilliance versus Photon Energy for a storage ring of 6 GeV Energy and 100 mA current.

synchrotron sources, up to $\sim 10^{10}$ larger than X-ray tube, mostly due to much smaller angular divergence. This is important because many experiments use small samples (e.g. protein crystals!) that can use only a tiny fraction of radiation emitted by tube. Much higher intensity make possible to observe very weak signals not observable with tube source, much tighter angular collimation is especially important for small samples, e.g. protein crystals, high pressure applications, etc. (Giacovazzo, 2002). By the use of special optical elements, such as monochromators, single energies can be selected among the continuous spectrum of Synchrotron Radiation; this energy tunability is of extremely importance especially for experiments driven near the absorption edge of specific elements.

Fourth generation light sources

The development of Fourth Generation Light Sources has been pointed out on Free Electron Lasers (FELs) (Pellegrini and Stöhr, 2003; Pant, 2015; Freund and Antonsen, 2018). Such sources produce radiation with brightness several orders of magnitude higher than undulators on third-generation rings. Graph in Fig. 9 shows the trend of the growth of the brilliance of X-ray sources starting from the beginning of the XX Century.

Radiation from a FEL has much in common with radiation from a conventional optical laser, such as high power, narrow bandwidth and diffraction limited beam propagation. One of the main differences between the two lasers is the gain medium: in a conventional laser the amplification comes from the stimulated emission of electrons bound to atoms, either in a crystal, liquid dye or a gas, whereas the amplification medium of the FEL are “free” (unbound) electrons. The free electrons are stripped from atoms in an electron gun and are then accelerated to relativistic velocities. While the electrons are propagating in an undulator the interaction with an electromagnetic radiation field leads to an exponential growth of the radiation emitted by the electrons. This amplification of radiation is initiated by an increasingly pronounced longitudinal density modulation of the electron bunch. The initial radiation field can be an external one, e.g. a seed laser, or an “internal” field, i.e., the spontaneous emission of the undulator. In the latter case it is called a SASE (Self Amplified Spontaneous Emission) FEL. Oscillating through the undulator, the electron bunch then interacts with its own electromagnetic field created via spontaneous emission. Depending on the relative phase between radiation and electron oscillation, electrons experience either a deceleration or acceleration: electrons that are in phase with the electromagnetic

Fig. 9 Trend of the Brightness of X-ray sources plotted starting from the beginning of 1900.

wave are retarded while the ones with opposite phase gain energy. Through this interaction a longitudinal fine structure, the so-called micro bunching, is established which amplifies the electromagnetic field. The longitudinal distribution of electrons in the bunch is “cut” into equidistant slices with a separation corresponding to the wavelength λ_{ph} of the emitted radiation, which causes the modulation. More and more electrons begin to radiate in phase, which results in an increasingly coherent superposition of the radiation emitted from the micro-bunched electrons. The more intense the electromagnetic field gets, the more pronounced the longitudinal density modulation of the electron bunch and vice versa. The characteristics of FEL radiation are high power, short pulse length (pico to femtoseconds), narrow bandwidth, spatial coherence and wavelength tunability. Of particular importance are detectors capable of measuring such fast and intense signals (Knoll, 2012; Antonelli et al., 2013). Technology is constantly advancing in the construction of these devices.

Laser plasma X-ray sources

The concept for X-ray lasers goes back to the 1970s, when physicists realized that laser beams amplified with ions would have much higher energies than beams amplified using gases. Nuclear explosions were even envisioned as a power supply for these high-energy lasers. In X-ray lasers (Umstadter, 2015), a pulse of light strikes a target, stripping its atoms of electrons to form ions and pumping energy into the ions (“exciting” or “amplifying” them). As each excited ion decays from the higher energy state, it emits a photon. Many millions of these photons at the same wavelength, amplified in step, create the X-ray laser beam. Compact short-pulse high-power X-ray sources can be produced by focusing on a solid target ultra short laser pulses of low or moderate energy (from several to ten or a hundred millijoules) but of high intensity ($\geq 10^{15} \text{ Wcm}^{-2}$). For example, subpicosecond laser pulses can produce X-ray pulses of high power and short duration (in the picosecond range). With respect to hard and soft X-ray emission, such laboratory X-ray sources offer the following advantages over conventional X-ray sources such as synchrotrons: a greater compactness, an easier access, a lower cost, a shorter pulse length and a smaller source size.

Conclusion

The future of the research in the field of X-ray sources will be more and more bonded to the possibility to manipulate optically the radiation and to obtain a selective detection of the photons in order to perform ever more accurate spatial and temporal analysis. The use of these new methodologies of detection is already allowing to develop new X-ray sources and to study new physical phenomena until now inaccessible.

Abstract

Neutrons are a very elusive and versatile probe for the investigation of the microscopic properties of materials in basic research and for technological applications. In the following we provide an overview of the status and the future of high-flux neutron sources and the progress made in the development of the extraction of intense neutron beams for experiments using advanced neutron optics based on high-performance supermirrors. Despite the significant progress made during the last years, the maximum neutron flux seems to saturate at a peak flux of the order of $10^{17} - 10^{18}$ neutrons per cm^2 and per s.

- Prospects for future neutron sources

Introduction

Neutron scattering (Furrer et al., 2009; Shirane et al., 2002) is one of the key scattering techniques for the investigation of the static and dynamic properties of materials in solid state physics. In addition, neutrons are also a valuable tool for imaging of materials, (Kardjilov et al., 2018) for solving fundamental questions in particle physics, (Chupp et al., 2019; Dubbers and Schmidt, 2011) and for irradiation (Tarantini et al., 2006) and activation experiments (Greenberg et al., 2011). Clearly, the quality and the precision of experiments with neutrons are determined by the available neutron flux.

The history of neutron sources has seen a tremendous increase of the thermal neutron flux density Φ_{th} of fission reactors from $10^7 \text{ cm}^{-2} \text{ s}^{-1}$ in 1942 at the Chicago Pile CP1 to $\simeq 10^{15} \text{ cm}^{-2} \text{ s}^{-1}$ at the HFR at the ILL in 1972 (ILL, 1986). Since then, due to limitations in the power density, no further progress has been reported (Fig. 1). Indeed, for the production of one neutron, an energy of approximately 200 MeV is released.

In contrast, the spallation process releases only about 20 MeV per neutron thus allowing to increase Φ_{th} by approximately an order of magnitude. For pulsed neutron beams produced by spallation, peak flux densities of the order of $\hat{\Phi}_{th} \simeq 10^{17} \text{ cm}^{-2} \text{ s}^{-1}$ can

[☆]Change History: November 2022. P Böni updated the chapter.

Fig. 1 Peak neutron flux density $\hat{\Phi}_{th}$ of some typical neutron sources. Inserted are also the performances of the recently proposed accelerator-based sources namely the source based on halo neutrons, i.e., neutrons in highly excited states orbiting the nucleus at large radii (Habs et al., 2011) and the compact source HBS (Brückel and Gutberlet, 2020; Gutberlet et al., 2020). Open symbols indicate neutron sources that are not yet in operation or are in a conceptual phase. After Böni P, and Petry W (2018) Neutron science with highly brilliant beams, Chapter 20. In Bolton P, Parodi K, and Schreiber J. (Eds.), *Applications of Laser-Driven Particle Acceleration*, pp. 314–330. CRC-Press Taylor & Francis Group: Boca Raton, FL, USA. ISBN 9781498766418. <https://www.crcpress.com/Applications-of-Laser-driven-Particle-Acceleration/Bolton-Parodi-Schreiber/p/book/9781498766418>. (Please note that the figure has been modified when compared with the cited one.)

be achieved. At the spallation sources SNS at Oak Ridge National Laboratory (SNS, 2019) and J-PARC in Tokai (JPARC, 2019) a peak flux density of $\simeq 2 \cdot 10^{16} \text{ cm}^{-2} \text{ s}^{-1}$ has been realized, which is expected to be surpassed by the future European Spallation Source (ESS, 2019) by about a factor of three. Similarly as for reactors, the maximum flux density is converging too, namely toward a value $\hat{\Phi}_{th} \simeq 10^{17} \text{ cm}^{-2} \text{ s}^{-1}$ (Fig. 1).

Therefore, the prospects of increasing $\hat{\Phi}_{th}$ significantly are rather grim and future progress has to be achieved by other means, for example by optimizing all components, which bring the neutrons from the source to the experiment. This situation is in strong contrast to synchrotron sources and free electron lasers which witness a steady increase in photon flux by orders of magnitude during the recent years (Shin, 2021). Further progress in increasing the neutron flux significantly seems to be possible only by the development of new concepts of neutron production, for example by direct conversion of particle beams into cold or thermal neutrons circumventing the moderation process.

In the following we start by summarizing the unique character of neutron scattering for the investigation of the static and dynamic properties of condensed matter followed by a survey of the historical evolution of neutron sources and an introduction into the basic principles of neutron production and their properties. The next chapter deals with the moderation of the neutrons reducing their original energy from the MeV to the meV range. Finally we discuss means for the extraction and the transport of neutrons from the moderator to the experiments followed by a discussion of future prospects of neutron sources in the concluding section.

Neutron scattering for condensed matter research

The principle of the scattering of particles by a sample is the same for most kinds of radiation. The geometry of a scattering experiment is shown in Fig. 2. Incident particles (neutrons, photons, electrons, etc.) having a wavevector $\mathbf{k}_i$ and a flux density Φ

Fig. 2 Geometry for a scattering experiment. A plane wave of radiation that propagates along the z -direction is scattered by the sample into a solid angle $d\Omega$.

(unit: $\text{m}^{-2} \text{s}^{-1}$) are scattered by the sample into the solid angle $d\Omega = \sin \theta d\theta d\phi$ (unit: sr). Then the number of particles scattered per second into $d\Omega$ with wavevector $\mathbf{k}_f$ is given by

$$I = \Phi \left(\frac{d\sigma}{d\Omega} \right) d\Omega \quad \left(\frac{1}{\text{s}} \right). \quad (1)$$

Here, I and $d\sigma/d\Omega$ designate the intensity (s^{-1}) as measured by a detector covering a solid angle $d\Omega$, and the differential cross section ($\text{m}^2 \text{sr}^{-1}$), respectively.

In inelastic scattering experiments, the detector also measures the energy of the radiation, i.e., the double differential cross section (units: $\text{m}^2 \text{J}^{-1} \text{sr}^{-1}$)

$$I = \Phi \left(\frac{d^2\sigma}{d\Omega dE} \right) d\Omega_f dE_f. \quad (2)$$

can be determined. It contains information on the dynamical properties of the sample. Clearly, a high flux density Φ is essential to obtain reasonable counting statistics within a short time due to the selection of the energy. We note that the momentum and energy transfer to the sample are given by

$$\mathbf{Q} = \mathbf{k}_i - \mathbf{k}_f \quad (3)$$

$$E = E_i - E_f. \quad (4)$$

For the definition of the $\mathbf{Q}$ - and E -transfer during the course of an experiment, the range of the solid angle, Ω_i , and of the energy, E_i , of the incident radiation has to be restricted to $d\Omega_i$ and dE_i , respectively. To measure an optimum intensity, these quantities should be comparable with the resolution of the detecting system that is given by $d\Omega_f$ and dE_f . Note that $d\Omega_i$ and $d\Omega_f$ define the uncertainty of $\mathbf{k}_i$ and $\mathbf{k}_f$, namely $d\mathbf{k}_i$ and $d\mathbf{k}_f$, respectively and therefore the uncertainty of the transferred momentum $d\mathbf{Q}$.

Obviously, for measuring inelastic scattering, a high brilliance Ψ of the incident radiation

$$\Psi = \frac{d^4 N}{dA dt d\Omega dE} \quad \left(\frac{1}{\text{m}^2 \text{sr J}} \right) \quad (5)$$

is required. Here, N designates the number of neutrons. In terms of wavelength, the brilliance is given by

$$\Psi_\lambda = \frac{d^4 N}{dA dt d\Omega d\lambda} \quad \left(\frac{1}{\text{m}^2 \text{s sr } \text{\AA}} \right) \quad (6)$$

Knowing Ψ , the spectral flux density $\varphi(E)$ can be calculated by integrating Ψ about the solid angle encompassed by the neutrons illuminating the sample, i.e.,

$$\varphi = \Psi \Delta\Omega_i \quad \left(\frac{1}{\text{m}^2 \text{s}} \right). \quad (7)$$

Finally the flux density at the sample is given by

$$\Phi = \Psi \Delta\Omega_i \Delta E_i = \varphi \Delta E_i \quad \left(\frac{1}{\text{m}^2 \text{s}} \right), \quad (8)$$

i.e., for a high $\mathbf{Q}$ - and E -resolution, Φ becomes very small.

Let us estimate the number of neutrons per second impinging a sample during the course of a typical inelastic neutron scattering experiment. We assume the following configuration: $\lambda_i = 5 \text{ \AA}$, $\Delta\lambda_i = 0.05 \text{ \AA}$ and $\Delta\Omega_i = 4 \cdot 10^{-4} \text{ sr}$. Taking the spectral flux density of cold neutrons from the "Blue Book" of the FRM II (see also Fig. 10), (FRM II, 2011), i.e., $\varphi_c = 1.2 \cdot 10^{13} \text{ cm}^{-2} \text{s}^{-1} \text{\AA}^{-1}$ (corresponding to $\Psi_c \simeq 1 \cdot 10^{12} \text{ cm}^{-2} \text{s}^{-1} \text{\AA}^{-1} \text{sr}^{-1}$) one obtains for a beam size of 1 cm^2 an intensity of $I = 2 \cdot 10^7 \text{ s}^{-1}$.

For the development of new materials and processes, a detailed knowledge of the microscopic processes on an atomic scale is required and scattering techniques are obviously a powerful means to obtain microscopic information about the static and dynamic properties of the sample.

Among all the scattering techniques, neutrons have outstanding properties. The most relevant, unique character of thermal neutrons, which can hardly be matched by any other experimental technique, can be summarized as follows:

- (i) Neutrons interact with the nuclei and are therefore sensitive to light and heavy atoms. Moreover, isotopic substitution enables adjustment of the scattering contrast thus allowing for example to highlight the functionality of parts of large macromolecules.
- (ii) The wavelength of thermalized neutrons is of order of atomic lengths, thereby ideally suited to make visible these dimensions.
- (iii) The energy of thermal neutrons is of order of the energy of elementary excitations in condensed matter. Therefore the dynamic properties of materials, which are relevant at room temperature, can be measured with high accuracy.
- (iv) As neutrons have no charge, their penetration depth is large for most materials. Therefore, the volumetric properties of materials can be identified. Moreover, studies under extreme conditions such as high pressure and high magnetic fields can be performed.
- (v) In first order the interaction of neutrons with matter is a nuclear process, i.e., it depends on the particular isotope thereby allowing a distinction of isotopically labeled molecules in an environment of chemically identical molecules.
- (vi) Because of the weak interaction strength, neutrons do not cause significant radiation damage and the cross sections can be interpreted in most cases in terms of linear response theory. In addition, the data can be put on an absolute scale facilitating the interpretation.

- (vii) Neutrons carry a magnetic moment and are thus very sensitive to the static and dynamic magnetic properties of materials.
 (viii) Finally, thermal neutrons might be absorbed by a nucleus and induce a nuclear reaction, thereby creating radio isotopes.

The quality and precision of neutron scattering experiments is primarily determined by the counting rate and, therefore, by the brilliance of the neutron source and the transport system bringing the neutrons to the sample. Although about half of our world is made up of neutrons, they are tightly bound in the atomic nucleus and quite difficult to set free. Facilities that accomplish this task in a manner useful for scientific and technological applications are called neutron sources.

Historical evolution of neutron sources

Because free neutrons have only a lifetime of about 15 min (Greene and Geltenbort, 2016), they have to be released for applications continuously by means of nuclear reactions. Table 1 lists some processes that can be used for the production of neutrons. Clearly, for a high brilliance, reactions with a minimal deposited heat are preferred in order to reduce the power generation.

Neutrons were observed for the first time by Chadwick in 1932 (Chadwick, 1932). He illuminated beryllium with alpha particles, which are released during the decay of natural polonium. Indeed, most early neutron sources for neutron physics research used alpha radiation.

In order to increase the neutron flux, nuclear fission reactors were invented. Initially, they were constructed for research in nuclear industry rather than for neutron scattering that was a kind of unforeseen spin off. The development started in 1942 with the Chicago Pile 1 that yielded a thermal neutron flux density $\Phi_{th} = 10^7 \text{ cm}^{-2} \text{ s}^{-1}$ (CP-1, USA) and had its climax in 1972 when the high-flux reactor at the Institute Laue-Langevin (ILL) in Grenoble was taken into operation yielding $\Phi_{th} = 1.2 \cdot 10^{15} \text{ cm}^{-2} \text{ s}^{-1}$. This facility was dedicated for neutron scattering and the study of the fundamental properties of the neutron.

Meanwhile, pulsed sources, starting with Alvarez's use of an rf-pulsed cyclotron, and in particular electron accelerators that produce neutrons through bremsstrahlung have been increasingly applied for research with slow neutrons. In addition, pulsed reactors have been developed. However, all these facilities could not really compete with the overall performance of the HFR reactor (ILL), or the HFIR (Oak Ridge) and HFBR (Brookhaven) in the US, except perhaps the pulsed reactor IBR-2 at Dubna (Russia) that produces thermal peak flux densities up to $\Phi_{th} = 10^{16} \text{ cm}^{-2} \text{ s}^{-1}$ in pulses several hundred microseconds long.

Today the most intense pulsed neutron sources are based on powerful proton accelerators that produce high peak flux densities by spallation (Andersen et al., 2020). Presently the world-wide leading facilities are the SNS in Oak Ridge (USA) and J-PARC in Tokai (Japan), which provide a peak flux density of the order of $10^{16} \text{ cm}^{-2} \text{ s}^{-1}$ with short pulse lengths of the order of 50 μs and a repetition rate of 60 Hz. Next-generation pulsed neutron sources, such as ESS (Lund, Sweden) and STS-SNS (Oak Ridge) with a peak flux density approaching $10^{17} \text{ cm}^{-2} \text{ s}^{-1}$ are presently under construction or in the planning phase.

Production of neutrons

The primary goal of a neutron source is the release of as many neutrons as possible in a volume as small as possible to achieve a high brilliance Ψ . These requirements go along with the important demand that the heat deposition going along with the neutron release has to be minimized, since cooling problems are a limiting factor in practically all neutron source designs (see Fig. 1). In this respect fusion (Taylor et al., 2007) is by far the most optimal process for neutron production as can be seen from Table 1, followed by spallation and fission. Fusion may be the technique of neutron production in the far future, but today the two most commonly used reactions are (i) nuclear fission in ^{235}U with thermal neutrons and (ii) spallation by protons with an energy of about 1 GeV. In the next section we are going to introduce four concepts for neutron production.

Table 1 Neutron yields and deposited energy for some neutron-producing reactions (Furrer, 2005).

Reaction	Incident energy (MeV)	Yield (n/event)	Deposited heat (MeV/n)
T(d, n)	0.2	$8 \cdot 10^{-5} \text{ n/d}$	2500
W(e, n)	35	$1.7 \cdot 10^{-2} \text{ n/e}$	2000
$^9\text{Be(d, n)}$	15	$1.2 \cdot 10^{-2} \text{ n/d}$	1200
$^{235}\text{U(n, f)}$ (fission)	$3 \cdot 10^{-8}$	$\simeq 1 \text{ n/fission}$	200
(T, d) fusion	$\simeq 0.014$	$\simeq 1 \text{ n/fusion}$	3
Pb spallation	1 GeV	$\simeq 20 \text{ n/p}$	23
^{238}U spallation	1 GeV	$\simeq 40 \text{ n/p}$	50

The energy of the incident neutrons for fission corresponds to the energy of a thermal neutron. The incident energy of 14 keV for the fusion reaction corresponds to the temperature of the plasma at the minimum near the triple product (Lawson, 1955, 1957). After Furrer A (2005) Neutron sources. In Bassani F, Liedl GL, and Wyder P (Eds.), *Encyclopedia of Condensed Matter Physics*, pp. 69–75. Elsevier: Oxford. ISBN 978-0-12-369401-0. <https://doi.org/10.1016/B0-12-369401-9/00633-1>. <https://www.sciencedirect.com/science/article/pii/B0123694019006331>.

Fission sources

Fission of the uranium isotope ^{235}U by the capture of thermal neutrons is still the most frequently used process for the provision of high-intensity neutron beams. The reaction can be made self-sustaining because it is exothermal and releases typically $\eta_f = 2.42$ neutrons per fission process, i.e., more neutrons than needed to sustain a chain reaction. At capture, the resulting deformation of the U causes the nucleus to break into two fragments (Fig. 3). Most neutrons are released directly during this process while 0.65% of the neutrons are released with a delay of a few tens of seconds from the daughter nuclei. The delayed neutrons are an important feature of the fission process because they enable a critical arrangement to be run in a controlled fashion.

The spectral distribution of the fission neutrons can be parametrized by the normalized Watt spectrum (Fig. 4)

$$f_W(E)dE = C \sinh(\sqrt{bE}) e^{-aE} dE. \quad (9)$$

The parameters are given by $a = 1.0124 \text{ MeV}^{-1}$, $b = 2.1893 \text{ MeV}^{-1}$, and $C = 0.4524 \text{ MeV}^{-1}$ (Emendörfer and Höcker, 1969). f_W can also be well approximated by a Maxwell-Boltzmann distribution with a thermal energy $E_{th} = k_B T = 1.29 \text{ MeV}$

$$f(E) dE = 2 \left(\frac{E}{\pi(k_B T)^3} \right)^{1/2} e^{-E/k_B T} dE. \quad (10)$$

Because the wavelength of the fission neutrons is not matched to atomic distances in materials, they are not useful for neutron scattering as explained in section “Moderation of neutrons.”

Let us estimate the neutron production per second as follows

$$N_f = \eta_f \frac{P}{E_f}, \quad (11)$$

where P is the thermal power of the reactor and $E_f = 200 \text{ MeV}$ is the energy released during a fission process (Table 1). Obviously, the neutron production scales with P . Assuming a power of 20 MW and $\eta_f = 2.42$ one obtains $N_f = 1.5 \cdot 10^{18} \text{ s}^{-1}$. One of the neutrons is required for maintaining the chain reaction and some neutrons are lost due to absorption and leakage, leaving essentially one neutron per fission process left over for experiments, i.e., $N_f^{eff} = 6.2 \cdot 10^{17} \text{ s}^{-1}$. Usually, the fuel element is placed inside a tank of about 2500 L of D_2O yielding an equilibrium neutron density of $n_f \simeq 2.4 \cdot 10^{11} \text{ cm}^{-3}$. Obviously, due to limitation

Fig. 3 Schematic representation of the fission process of ^{235}U . From Furrer A (2005) Neutron sources. ISBN 978-0-12-369401-0. <https://doi.org/10.1016/B0-12-369401-9/00633-1>. <https://www.sciencedirect.com/science/article/pii/B0123694019006331>.

Fig. 4 Fast fission spectrum of ^{235}U . The Watt spectrum can be well approximated by a Maxwell-Boltzmann distribution function with a thermal energy $E_{th} = 1.29 \text{ MeV}$.

in the heat transfer, the power of neutron sources is limited. This is the reason, why the proposal to construct a high-brilliance neutron source with a power of 300 MW, the Advanced Neutron Source (ANS) in the US, was canceled in 1995 (Rush, 2015).

Spallation sources

The term “spallation” is applied to a sequence of events that occur when heavy target nuclei are bombarded with high energy particles with a de Broglie wavelength $\lambda_{dB} = \sqrt{h^2/(2mE)}$, which is shorter than the diameter of the nuclei (Fig. 5). Therefore, collisions can take place with individual neutrons and protons inside the nuclei and large amounts of energy are transferred to them which, in turn, can hit other neutrons and protons within the same nucleus. The net effect of this intra-nuclear cascade is twofold: Firstly, energy is more or less evenly distributed over the nucleus leaving it in a highly excited state; secondly, energetic neutrons and protons may leave the nucleus and carry the cascade on to neighboring nuclei (inter-nuclear cascade) or escape from the target. The excited nucleus left behind will start to evaporate neutrons and to a lesser extent protons.

The low-energy part of the spectrum of these evaporation neutrons is quite similar to the one resulting from fission (Eq. 9), but as a consequence of the neutron escape during the intra-nuclear cascade, the spectrum extends to energies up to that of the incident particles that is of the order of 2 GeV. The release of spallation neutrons takes place within less than 10^{-15} s after the nucleus is hit, so that the time distribution of spallation neutrons is exclusively determined by the time distribution of the driving particle pulse.

Modern spallation sources are usually driven by protons from a linear accelerator (linac). The process starts at the front end of the linac with the creation of negatively charged hydrogen ions by powerful ion sources. As they are electrically charged these hydrogen ions can be accelerated by radio frequency cavities to kinetic energies in the GeV range, which corresponds to about 90% of the speed of light. When this highly energetic particle stream exits the linac, the hydrogen ions are stripped off their electrons by letting them pass through a thin carbon foil, turning the hydrogen ions into protons. The pulse length of the proton bunches is typically $t_{linac} \simeq 1$ ms.

If short neutron pulses are required, as for example for short-pulse spallation sources (SPSS), such as ISIS, SNS, or J-PARC, the protons are fed into a compressor ring (typical diameter 200 m), which accumulates the protons from a large number of successive bunches as delivered by the linac into single high intensity proton pulses. For this purpose an assembly of magnets bends each accelerated proton bunch onto a circular orbit such that the next bunch of protons arrives exactly when the previous has gone once around. In this way all these bunches pile up.

After about 1000 revolutions sufficient intensity is accumulated, and the full proton pulse with a pulse length of $t_{SP} \simeq 1 \mu\text{s}$ is extracted and propelled toward the target, which is usually a solid target (Ta, W) or a liquid metal (mercury or a lead-bismuth eutectic mixture (Latge et al., 2016) to take up the beam power of the order of 1 MW. This whole process from the creation of the hydrogen ions to the arrival of the highly energetic protons at the target occurs with a pulse repetition rate in the range 10–100 Hz in order to achieve an optimal neutron economy in scattering experiments. As explained in section “Moderation of neutrons” after moderation, the pulse length of the neutrons will be with 50 – 150 μs much longer than the proton pulse due to the slowing down process in the moderator.

At SNS, assuming a power $P = 1$ MW, an energy of about 20 kJ is deposited per proton pulse within about 1 μs corresponding to an instantaneous power $P_{SP} \simeq 20$ GW leading to a strong erosion of the liquid metal container by cavitation (Naoe et al., 2020). Moreover, very large space charges develop in the accumulation ring thus limiting further progress with this technology.

As suggested by Mezei (1997), a given beam power can be achieved at significant lower costs if the protons emerging from a linac are directly used for the spallation process. The long pulse of the order of ms allows to deposit a much higher beam energy per pulse

Fig. 5 Schematic representation of the spallation process of heavy nuclei. From Furrer A (2005) Neutron sources. In Bassani F, Liedl GL, and Wyder P (Eds.), *Encyclopedia of Condensed Matter Physics*, pp. 69–75. Elsevier: Oxford. ISBN 978-0-12-369401-0. <https://doi.org/10.1016/B0-12-369401-9/00633-1>. <https://www.sciencedirect.com/science/article/pii/B0123694019006331>.

Fig. 6 Time structure of neutron pulses as produced at a SPSS and at a long-pulse spallation source (LPSS). At the ESS (ESS, 2019) the neutron pulses have a length of 2.86 ms. If shorter pulses are required they can be selected by chopping the beams (triangle in orange). After Andersen K (2013) *Reactor & Spallation Neutron Sources Website*. https://www.oxfordneutronschool.org/2013/Lectures/Andersen-Neutron_Sources.pdf.

on the target thus leading to a higher neutron flux density (Fig. 6). If shorter neutron pulses are required, they can be selected according to the requirements of the experiments by using choppers thus providing a tremendous flexibility (Andersen et al., 2020).

For example, the future neutron source ESS with a power of 5 MW will deliver pulses with an energy of 360 kJ and a length of 2.86 ms at a repetition rate of 14 Hz to a rotating target made from tungsten (Andersen, 2013). Therefore, the instantaneous power is only 0.13 GW per proton pulse, i.e., about two orders of magnitude smaller than for a SPSS. Still, the dissipation of heat from the target will be a factor limiting the flux density of long pulse spallation sources (Fig. 1).

Compact neutron sources

Nuclear reactors and spallation sources for research are usually only available at large neutron scattering centers due to the complexity of their operation and the large financial investments. An alternative route to obtain brilliant neutron beams is based on nuclear reactions using low energy electron, proton or deuteron beams hitting a target composed of light or heavy elements (Fig. 7). Because of the low nuclear inventory of these facilities, nuclear licensing is less critical and the shielding requirements are small.

One of the first accelerator based facilities started operation in Bariloche (Argentina) in 1969 (Rodríguez Palomino et al., 2013). An electron linac accelerated electrons up to 25 MeV at a current of $30 \mu\text{A}$, which were directed on a Pb target yielding a neutron beam with an intensity of approximately $6 \times 10^{11} \text{ s}^{-1}$. Since then, due to significant scientific and technological advances in accelerator and target technology, the particle currents could be strongly increased, i.e., up to 50–100 mA thus providing neutron beams with a high brilliance. The pulsed beams have typically a frequency between 10 and 300 Hz that can be adjusted to the needs of the experiment.

Compact neutron sources are in operation in the US and in Japan since the 90s (Table 2). A detailed overview can be found in the paper by Anderson et al. (2016). Recently, several projects for compact accelerator driven neutron sources have been proposed in Europe such as HBS at JCMS and SONATE at LLB (ELENA, 2022; Table 2).

At most existing facilities, protons are accelerated to energies of the order of 10 MeV providing currents of a few tens of mA on a Be target. Recently, Rucker et al. proposed the reaction (Rucker et al., 2016).

Fig. 7 Neutrons are released from a target nucleus after being hit by protons or deuterons with an energy of the order of 10–70 MeV. From <https://elena-neutron.iff.kfa-juelich.de/neutron-facilities/>.

The released neutrons will be thermalized in small moderators with a thickness $t \simeq 1$ cm. They can be individually designed for the foreseen application such as for diffraction, spectroscopy, SANS, imaging, etc. It is expected that the performance of instruments at these compact accelerator driven neutron sources may become competitive with existing medium-flux neutron sources (Fig. 1).

The Jülich High Brilliance Neutron Source (HBS) represents one of the most advanced projects to deliver neutron beams with a high brilliance (Brückel and Gutberlet, 2020). Here, a proton beam with a high current of 100 mA is accelerated to an energy of 70 MeV and directed to several target stations which provide neutrons for moderators, which are optimized for the various beam lines. The use of a Ta target instead of Be increases the yield per proton by a factor of 2–3, i.e., a neutron intensity of the order of 10^{15} s^{-1} is expected. At a beam current of 100 mA, a neutron flux density of the order of $5 \cdot 10^{14} \text{ cm}^{-2} \text{ s}^{-1}$ may be obtained. Therefore, beamlines at the HBS are expected to be competitive with beamlines at present day research reactors of medium size spallation sources (Brückel and Gutberlet, 2020).

Halo neutrons

Conventional neutron sources suffer from at least two drawbacks: Firstly, the neutrons are emitted essentially into a solid angle of 4π when they are produced by the nuclear reaction and slowed down in the moderator. Therefore, only a fraction of $\simeq 10^{-5}$ of the produced neutrons can be extracted from the moderator and brought to an experiment. Secondly, the size of the neutron source is much larger than typical sample volumes, which are of the order of a few cubic centimeters. Ideally, a neutron source should be designed emitting thermal neutrons as a beam in a well defined direction.

A concept proposed by Habs et al. is based on the idea of producing neutrons by means of the emission of low energy neutron beams from neutron halo isomers of stable nuclei (Habs et al., 2011). These isomers may provide beams with a high brilliance. As shown in Fig. 8, a narrow-band γ -beam with a high intensity hits target nuclei and excites neutrons to a halo state, i.e., to an energy level directly below the ionization threshold. Finally, low energy neutrons from these long-lived states (100 ps - μs) can be released in pulses or quasi-continuously by photons in the visible or X-ray regime along the direction of the electric field vector, for

**Fig. 8** Neutrons are released from target nuclei in two steps: excitation of photo neutrons by γ -photons from an ERL followed by ionization by a laser-photons.

example by a laser. The γ - rays can be produced by Compton back-scattering of laser beams off brilliant electron beams as produced by energy recovery linacs (ERL) (Hajima et al., 2009).

According to Habs et al. (2011), using present day technology, an up to a 10^2 - to 10^6 - fold increase in brilliance may be achieved when compared with fission and spallation sources, respectively, using accelerator technology that will become available in the near future.

Because the targets for neutron production have only a diameter of typically a few tens of mm, the total number of produced neutrons per second (or pulse) will be much smaller when compared with conventional sources, however, much more confined in space leading to an exceptionally high brilliance.

As has been witnessed for sources of synchrotron radiation, the further development of accelerators, for example by laser-driven technology, will help to increase the brilliance even further. Clearly, to make this concept work, suitable neutron halo isomers, i.e., nuclei that allow neutron excitation much beyond the nuclear core radius, have to be identified. A list of suitable rare-earth nuclei has been proposed (Habs et al., 2011).

Neutron energies and properties

The energy range of the neutrons available in neutron sources spans many orders of magnitude. Table 3 provides a summary of denominations commonly used to label various regimes of neutron energy.

Table 4 summarizes the basic properties of the neutron as well as some useful physical constants and relations regarding thermal neutrons.

Table 3 Neutrons classified by their energy, velocity, and wavelength.

Classification	Energy (meV)	Velocity (m/s)	Wavelength (Å)
Ultra cold (UCN)	≤ 0.1	< 140	> 28
Very cold (VCN)	0.1–0.5	140–310	13–28
Cold	0.5–5	310–980	4–13
Thermal	5–100	980 – 4'400	0.9–4
Hot (epithermal)	100–1000	4'400 – 14'000	0.29–0.9
Resonant	$10^3 - 10^5$	14'000 – 140'000	0.029–0.29
Classification	Energy (MeV)	Velocity (km/s)	Wavelength (fm)
Intermediate	$10^{-3} - 0.5$	440–9800	40–900
Fast	0.5–10	9'800 – 44'000	9–40
Very fast	10–50	44'000 – 98'000	4–9
High energy	$50 - 10^4$	98'000 – 1.4 Mio	0.29–4
Relativistic	$> 10^4$	≥ 1.4 Mio	≤ 0.29

Neutrons with energies up to approximately 1 eV are typically used for neutron scattering, imaging, and fundamental physics. The high energy neutrons (50 MeV–10 GeV) are also called ultra fast neutrons.

Table 4 Neutron properties and important constants.

Parameter	Variable	Numerical value	Unit
Mass	m_n	$1.674927498 \times 10^{-24}$	kg
Charge	Q	0	C
Spin	S_n	1/2	
Magnetic moment	μ_n	$-9.662365 \cdot 10^{-27}$	J/T
Nuclear magneton	μ_N	-1.9130427	μ_N
		$5.05078370 \cdot 10^{-27}$	J/T
		$3.15245126 \cdot 10^{-5}$	meV/T
Lifetime of neutron	τ	7.62259329	MHz/T
		879.4	s
Zyla et al. (2020)			
Boltzmann constant	k	$1.3806504 \cdot 10^{-23}$	J/K
		0.08617087	meV/K
Elementary charge	e	$1.602176634 \cdot 10^{-19}$	C
Planck constant	h	$6.62607015 \cdot 10^{-34}$	Js
		$4.13566770 \cdot 10^{-12}$	meV s
Composition	quarks	udd	

For the calculation of the conversion factors, the parameters E , λ , k , and v are given in meV, Å, Å⁻¹, and km, respectively.

Conversion factors: $E = 81.81 \cdot \lambda^{-2} = 2.072 \cdot k^2 = 5.227 \cdot v^2$

Energy scales: $1 \text{ meV} = 0.242 \text{ THz} = 8.07 \text{ cm}^{-1} = 11.6 \text{ K}$.

Moderation of neutrons

As discussed in section “Production of neutrons,” the energy of neutrons released by nuclear reactions is in the MeV range, whereas neutrons with an energy of meV are required for most experiments. Therefore, an energy shift by about 9 orders of magnitude is necessary that can be accomplished by collisions of neutrons with light nuclei in a moderator.

In research reactors, the fast neutrons are thermalized in a moderator that surrounds the fuel element. Part of the neutrons are used to maintain the chain reaction and the others are extracted by beam tubes pointing into the moderator (Fig. 9). The preferred moderator is D₂O due to its low absorption and the small mass of the deuterium atoms yielding an efficient thermalization within about 21 collisions. Usually, the volume of the moderator is large thus bringing the neutrons close to the thermal equilibrium. To reduce the background of fast neutrons, the beam tubes are arranged tangential to the fuel element.

At short-pulse spallation and compact neutron sources, the neutrons should be thermalized within as short a time as possible to guarantee short neutron pulses. Therefore, hydrogen containing materials such as water, H₂ or methane encompassing small volumes of a few liters are used to provide the short required thermalization times (Fig. 9). Usually, the neutrons do not reach a thermal equilibrium yielding a pronounced tail of epithermal neutrons, which are useful for certain experiments.

Currently, the trend goes toward small “high-brilliance moderators,” such as the flat pancake shaped para-hydrogen moderator at the ESS (Andersen et al., 2018; Zanini et al., 2019) or the finger-moderators (Cronert et al., 2016) for compact accelerator-or photon based neutron sources (Carpenter, 2019). The small shape yields not only an increase in brilliance, it also provides an enhanced emission of neutrons in particular directions.

In the following we assume that the neutrons attain a thermal equilibrium with the moderator. Therefore, the velocity distribution of the neutrons is given by the Maxwell-Boltzmann distribution function (compare with Eq. (10))

$$f(v) \cdot dv = 4\pi \left(\frac{m_n}{2\pi kT} \right)^{3/2} v^2 e^{-\frac{m_n v^2}{2kT}} dv \quad (13)$$

where m_n is the mass of the neutron. $f(v)dv$ is the number of neutrons within a velocity interval dv having a velocity v . Moderators are usually kept at room temperature and this is why the extracted neutrons are called thermal neutrons.

Fig. 9 Moderator configurations for four types of neutron sources. The moderators for fission sources are large to bring the neutrons close to the thermal equilibrium. To warrant a short pulse width at spallation sources and CANS, small moderators are used yielding under-moderated beams. The volumes of the targets anticipated for the (γ, n) reaction are of the order of 1 mm³ yielding highly brilliant beams. Neutron guides may be used to extract neutrons. For full illumination, their entrance has to be moved as close as possible to the neutron source.

The yield of experiments requiring cold neutrons can be significantly improved by shifting the velocity spectrum of the neutrons to smaller energies by inserting a vessel containing liquid D₂ and H₂ with a temperature $20\text{ K} \leq T \leq 50\text{ K}$ into the D₂O moderator of a reactor or placing it close to the target of a spallation target (Fig. 9). For hot neutrons, a block of graphite with a temperature $T \simeq 2000\text{ K}$ is inserted into the D₂O moderator. By choosing the adequate neutron spectrum the experiments with neutrons can be optimally tailored to the particular experimental requirements.

We have shown in section “Neutron scattering for condensed matter research,” that the number of detector counts during the course of an experiment is directly proportional to the spectral neutron flux density φ or the brilliance Ψ , which are related to each other according to Eq. (7).

Knowing the neutron density n , the flux density is given by

$$\Phi = n\langle v \rangle = n \int_0^\infty v f(v) dv. \quad (14)$$

Hence the spectral flux density is given by

$$\varphi = \frac{d\Phi}{dv} = n v f(v). \quad (15)$$

Inserting the Maxwell-Boltzmann equation yields

$$\varphi(v)dv = 4\pi n \left(\frac{m_n}{2\pi kT} \right)^{3/2} v^3 e^{-\frac{m_n v^2}{2kT}} dv \quad \left(\frac{1}{\text{cm}^3} \right), \quad (16)$$

i.e., knowing the neutron density, the temperature of the moderator, and assuming the neutrons to be in thermal equilibrium one can easily calculate φ . Finally, assuming that the neutrons are emitted isotropically, the brilliance $\Psi = \varphi/(4\pi)$ is obtained.

In neutron scattering experiments, it is often more convenient to express φ in terms of energy and wavelength

$$\varphi(E)dE = 2n \left(\frac{2}{\pi(kT)^3 m_n} \right)^{1/2} E e^{-E/kT} dE \quad \left(\frac{1}{\text{cm}^2 \text{SJ}} \right) \quad (17)$$

and

$$\varphi(\lambda)d\lambda = -8n \left(\frac{kT}{2\pi m_n} \right)^{1/2} \frac{\lambda_T^4}{\lambda^5} \cdot e^{-\frac{\lambda_T^2}{\lambda^2}} d\lambda \quad \left(\frac{1}{\text{cm}^2 \text{ sÅ}} \right), \quad (18)$$

respectively, where $\lambda_T = \frac{h}{\sqrt{2m_n kT}}$.

Fig. 10 shows the calculated spectra of the FRM II for hot, thermal and cold neutrons vs λ for moderator temperatures of 2000 K, 293 K, and 50 K, respectively. It is seen that using a neutron density $n_t = n_c = 2.4 \cdot 10^{11}$ (see section “Fission sources”) reproduces the spectral flux density of thermal and cold neutrons at the FRM II quite well (FRM II, 2011). For the hot spectrum, a reduced density $n_h = 2.4 \cdot 10^{10}$ had to be used. The deviations between the simple calculation and the measured spectra may be caused by the fact that there is still a significant contribution of under-moderated neutrons and that neutrons are scattered in and out of the cold and hot moderators. Anyway, the overall agreement is quite impressive.

Fig. 10 The spectral flux density $\varphi(\lambda)$ is shown for neutrons emerging from a cold (50 K), thermal (293 K) and hot (2000 K) moderator. The calculations (solid lines) are based on the assumption that the neutrons are in thermal equilibrium with the moderator. A neutron density $n_c = n_t = 2.4 \cdot 10^{11} \text{ cm}^{-3}$ is assumed for the cold and thermal flux density. For the hot flux density $n_h = 2.4 \cdot 10^{10} \text{ cm}^{-3}$ is assumed. The data is in reasonable qualitative agreement with the measured φ of the FRM II (solid symbols) (FRM II, 2011). Note that the brilliance Ψ is obtained by dividing φ by 4π .

Neutron beam transport

After moderation of the neutrons, it is necessary to transport them to the experiment positions, except for irradiation experiments, which are usually performed in-pile. Because conventional neutron sources radiate isotropically, they have to be surrounded by heavy biological shielding to protect the users. Beam tubes containing neutron optical components are inserted into the shielding to allow the neutrons to leave the moderator surface. It is essential that the beam tubes are arranged tangentially to the fuel or target region of the neutron source in order to reduce unwanted radiation, i.e., fast neutrons and γ -photons.

Originally, neutron beams were extracted by means of beam tubes (Fig. 11(a)), which did not contain any neutron optical components, yielding beams with a triangular divergence distribution with a width

$$\alpha_{BT} = \arctan(H/L) \simeq 1^\circ \quad (19)$$

when typical values for beam tubes, i.e., $H = 100$ mm and $L = 6'000$ mm, are used. Because of the resulting small solid angle, the neutron flux density available at the instrument position is drastically reduced by about five orders of magnitude when compared with the isotropic flux within the moderator, which is emitted into 4π . If the experiment is placed far away from the biological shielding, the flux decreases further by the squared inverse distance.

The flux at the instrument positions can be considerably improved by using neutron guides (Fig. 11(b)) (Maier-Leibnitz and Springer, 1963). A neutron guide works via total reflection of neutrons from the smooth walls of the guide material (Fermi et al., 1946). Total reflection occurs for scattering angles less than the critical angle of reflection θ_c , which is given by

$$\theta_c = \lambda \sqrt{\frac{\rho b}{\pi}}, \quad (20)$$

where ρ and b are the atom number density and the coherent scattering length of the wall material, respectively. Among common materials, nickel is the best choice with a critical angle $\theta_c = \kappa\lambda$, where $\kappa = 0.099$ deg/Å = 0.00173 rad/Å.

The angular acceptance of a neutron guide can be dramatically increased by coating the walls with so-called supermirror, which consists of a sequence of layers of variable thickness with alternating high positive and negative scattering length density (Mezei, 1976, 1992). Typical materials are Ni and Ti. Supermirror can be characterized by a number m defining the increase of $\theta_{c,m} = m\theta_c$ compared to nickel. According to Fig. 11(b), the divergence of the extracted neutrons is given by

$$\alpha_{SM} = 2m\kappa\lambda. \quad (21)$$

Of course, supermirror-coated guides are most efficient for neutrons with a large wavelength. For example, for $\lambda = 2$ Å and a coating $m = 4$ one obtains $\alpha_{BT} \simeq 1.6^\circ$ if reflection losses are neglected. If they are included, a trapezoidal divergence distribution is obtained (Fig. 11(b)). When compared to a beam tube, the gain in flux density when compared with an extraction by a beam tube is increased by a factor of $1.6^2 \simeq 2.5$. At present $m \simeq 8$ can be routinely achieved (Fig. 12) (Schanzer et al., 2016) resulting in a rather dramatic increase in neutron flux when compared with a conventional beam tube even for neutrons with a small λ . Further improvements in neutron extraction are achieved by means of elliptic or parabolic guides if their entrance can be properly illuminated (Böni, 2008).

Fig. 11 Beam extraction from a moderator using a beam tube (a), a fully illuminated neutron guide (b), an under-illuminated neutron guide (c), or a parabolic nested mirror optics (NMO). A NMO yields about a four times higher flux density than a neutron guide with identical supermirror coating. The figures on the right hand side show the divergence distribution of the extracted neutron beam.

Fig. 12 Reflectivity profiles of supermirrors with m -values $2 \leq m \leq 8$. The slope of R is largely independent of the m -value indicating a stable interface roughness, which is essentially constant for all layers From Schanzer C, Schneider M, and Böni P (2016) Neutron optics: Towards applications for hot neutrons. *Journal of Physics: Conference Series* 746: 012024-(1-7). <http://iopscience.iop.org/article/10.1088/1742-6596/746/1/012024/pdf>.

The current trend toward small “high-brilliance moderators”, such as the ones proposed for ESS and for compact accelerator based neutron sources, seems to be an obstacle for an efficient neutron extraction because of under-illumination of the guide entrance. According to Fig. 11(c), the wavelength dependent footprint (shown in one dimension) of transportable neutrons at the moderator position is given by

$$H_m = H + 2L_m \tan \theta_{c,m} \simeq H + 2L_m m \kappa \lambda. \quad (22)$$

Clearly, as soon as the size of the moderator, D , becomes smaller than H_m , illumination losses will occur leading to a dilution of the phase space of the neutrons indicated by the hatched trapezoid in Fig. 11(c). Therefore, the transfer of the brilliance from the source to the experiment is reduced. Hence, D has to be significantly larger than the size of the neutron guide for full illumination.

As proposed by Herb et al. (2022) the problem of under-illumination can be resolved by using an arrangement of nested elliptic or parabolic mirrors, which in contrast to elliptic guides or Montel mirrors provide an imaging of the moderator. As shown in Fig. 11(d), each mirror reflects neutrons emerging from a small angular range in the beam direction. All mirrors are fully illuminated and transform the incident divergent beam into a low-divergence beam that can be transported efficiently by a neutron guide which suffers only small reflection losses due to the small angles of reflection. Finally, the neutron beam can be refocused by nested mirrors at the position of the experiment.

The maximum divergence that is accepted by a parabolic system is given by

$$\alpha_{\text{NMO}} = \frac{H}{f} = 4m\kappa\lambda = 2\alpha_{\text{SM}}, \quad (23)$$

which is twice as large as achieved for an extraction by a conventional neutron guide. Therefore, an approximately fourfold increase in flux density is achieved. Moreover, the phase space is more compact. Even hot neutrons can be efficiently extracted using nested mirrors (Herb et al., 2022). It may well be that parabolic nested mirrors turn out to become the most efficient technique for neutron extraction presently available.

Conclusion

An ever growing scientific community uses neutrons in various disciplines of condensed matter research and fundamental physics, however, the currently active neutron sources (see Table 5) will not be able to supply the future demand at least not in Europe, where the number of neutron facilities has significantly decreased due to the recent shut-down of the Orphée reactor, BER II, and R-2 (Table 5). Moreover, further shut-downs of reactors taken into operation in the last century will happen in the near future. Most of these medium-flux neutron sources, which are indispensable (i) for experiments requiring a medium flux, (ii) for the education of scientists in neutron physics, and (iii) for the development of instrumentation will be sorely missed and cannot simply be replaced by the European Spallation Source ESS in Lund. Thus new sources, such as accelerator based compact neutron sources (CANS), are indispensable to ensure the continuity and further developments in neutron scattering. In contrast to Europe (with the exception of FRM II), new sources have been taken into operation in the US, Asia, and Australia in this century.

The history of the evolution of the neutron flux at fission sources was impressive until the high-flux reactor in Grenoble was commissioned. Since then a leveling off is observed that is caused by the technical difficulty of removing the heat from the reactor

Table 5 An incomplete list of neutron sources.

Startup	Facility	Location	Power (MW)	Peak flux density ($\text{cm}^{-2}\text{s}^{-1}$)	Type	Status
1932	Chadwick	Cambridge		1		Shut down
1934	0.35 mCi RaBe source			10,000		Shut down

The column "Peak flux density" provides the perturbed or unperturbed thermal peak flux density. For continuous sources, the peak flux density $\hat{\Phi}_m$ is equal to the average flux density Φ_{th} . The column "status" provides information on the status of the neutron source, namely shut down (the year is given if known to the author), in operation, under construction, funded, or proposed.

core (Fig. 1). A similar trend is observed for spallation sources, where the power may be limited to about 5–10 MW. Therefore, not much progress in the neutron flux can be expected by further developments on the source side. Only completely new concepts for neutron production, such as the fusion reaction (Taylor et al., 2007) or using halo isomers (Habs et al., 2011), can help to increase the flux significantly (Table 5). This situation is very different in comparison to X-ray synchrotron radiation where the flux is steadily increasing by orders of magnitude (Shin, 2021).

Due to the limitation of the flux density, most progress in increasing the performance of beam lines for neutron physics has been achieved by the development of new instrumental concepts and the improved transport of neutrons by neutron guides using supermirror. The use of nested mirror optics may prove to be the most efficient means for extracting neutrons from small high-brilliance moderators and focusing of neutrons. Here, a brilliance transfer of 25–70% may be achieved (Herb et al., 2022).

While most intensity gains are due to the increase of the divergence of the neutron beams, this development seems also to be limited because the ever increasing number of required layers for achieving a large m -value for supermirror, which is of the order of 16'000 atomically smooth layers for mirrors with $m = 8$, the ever increasing absorption by the layers is a limiting factor for increasing m further. Moreover, many experiments, such as studies of strongly correlated electron systems require high resolution in momentum and energy, thus preventing the use of neutron beams with a large divergence. Therefore, without the discovery of new concepts for neutron production, neutrons will indeed remain a flux limited probe making them very elusive and valuable.

Acknowledgments

I acknowledge the strong support of Albert Furrer for this work and providing his manuscript. It is with great pleasure to thank Thomas Gutberlet for useful discussions about Compact Accelerator-driven Neutron Sources and Christoph Herb and Oliver Zimmer for the collaboration in the field of nested mirror optics.

Abstract

Particle accelerators and sources are currently used for scientific, technological and medical applications. These devices provide low or high energy, charged or neutral particle beams employed as a function of their physical characteristics, like the current, the density, the beam duration, size and divergence. Electron sources play an important role in this context because they are easy particles to produce and because relatively simple technological systems of reasonable cost can be used to generate electron beams. Positron sources, have recently acquired an increasing interest in medical science and material diagnostics. In this chapter, the concept of particle source and the main designs and characteristics of electron and positron sources will be illustrated.

Key points

- Introduction of the particle source concept and the associated quality parameters
- Time structure of the electron beams
- Description of the different type of electron guns
- Description of the electron beams manipulation systems
- Overview of the future developments in electron sources
- Description of the positron production mechanisms
- Radioactive sources and energy moderation mechanism
- Positron photoproduction and beams separation
- Description of the main positron sources capture systems.

List of symbols

- B, B_n Brightness, normalized brightness
 β Reduced velocity v/c
 c Speed of light

γ	Lorentz factor
γ_{ph}	High energy photon
e	Electron charge
e^-, e^+	Electron, positron
E_o	Particle rest energy
E	Energy
E_e	Electron energy
ϵ, ϵ_n	Emittance, normalized beam emittance
I	Beam current
$I_b, \hat{I}_b$	Bunch current, peak bunch current
m_o	Particle rest mass
m_e	Electron rest mass
N	Number of particles
p, n	Proton, neutron
$\vec{P}, \vec{P}_o$	Momentum, nominal beam momentum
$\vec{p}$	Relative momentum deviation $\vec{P} - \vec{P}_o$
q	Charge
Q	Quality factor
QE	Quantum efficiency
r_e	Classical electron radius
s	Longitudinal coordinate
σ	Cross section
τ	Bunch duration
v	Velocity
V	Voltage
$e\phi_w$	Work function
$e\phi_{\text{eff}}$	Effective work function
ω_L	Laser frequency, laser photon energy
X_o	Radiation length
x, y	Horizontal, vertical coordinates
z	z stands for either x or y
Z	Atomic number

Introduction

A particle source is a device producing *particle beams* with well-defined and controlled intensity, divergence, mean energy and energy spread. Electron beams are used in science and technology to both investigate and modify matter, and as components of several electric and electronic devices. They are produced directly via *thermal*, photo or *field emission processes*. Positrons are mainly used in science and produced directly in radioactive decays or indirectly via *photon annihilation* in electron-positron pairs. Different types of sources are used for different applications.

Once produced, particle beams are accelerated by DC or alternating (RF) *electric field*, handled and transported using *electric* or *magnetic* components equivalent to lenses and prisms for light beams transport systems. One therefore speaks of *beam optics*. Because particles are charged, space charge, radiation and other possible forces between particles, including those mediated by the beam environment, have to be taken into account in addition to optical aberrations.

The main parameters characterizing a particle beam are energy E , energy spread ΔE , momentum, current I and brightness B . The beam current is defined as $I = qN\beta c$, q being the particle charge, βc the particle velocity and N the number of beam particles. Brightness is a measure of the current flowing through the unit area and solid angle and ultimately of the current that, for given energy spread and optics, can be focused onto a spot of given size: for given current, the higher the brightness the smaller the spot, down to the diffraction limit. A brief introduction to beam dynamics, given below, is required to precisely define the relations between these parameters.

Basic beam dynamics elements

The equivalent of the optical axis in a beam *optical* transport system is the trajectory followed by an ideal *reference particle* having the nominal beam momentum $\vec{P}_o$ and initial position $\vec{x}_o$ at the center of the magnetic quadrupoles. Position and momentum of the generic beam particle are defined relative to those of the reference particle and described by a point in the six dimensional phase space whose coordinates (x, p_x, y, p_y, s, p_s) are functions of the coordinate s along the trajectory, the reference particle always occupying

the origin. Introducing the familiar from optics angular coordinates x', y' , the prime indicating the derivative with respect to s the 6-D phase space reduces to $[x, \beta_\gamma x', y, \beta_\gamma y', s, p_s]$, with γ the reference particle Lorentz factor.

Let us now consider an ideal paraxial beam of N non-interacting particles (forces between particles negligibly small), subject only to external conservative forces (no radiation) with constant or slowly varying momentum P_0 and $p_x, p_y \ll P_0$. In this case the transverse $[x, \beta_\gamma x', y, \beta_\gamma y']$ and longitudinal $[s, p_s]$ phase space projections become (to first order in the coordinates) uncoupled and it can then be shown (*Liouville's theorem*) that the volume and area respectively occupied by the beam particles in each of the two projections are constants of motion. From the invariance of the beam occupied area in $[s, p_s]$ there follows that $\Delta E/I$ is a constant of motion. In transverse phase space let first consider a cylindrically symmetric beam with radius r and angular half aperture θ : the occupied volume $(\beta_\gamma)^2 \Delta S \Delta \Omega \approx \pi^2 (\beta_\gamma r \theta)^2 \approx \pi^2 \varepsilon_n^2$, with ΔS the beam cross section and $\Delta \Omega$ the beam subtended solid angle, is invariant and so is the here defined quantity ε_n called energy-normalized (or reduced) beam emittance. Note that because the invariant quantity is $\beta_\gamma r \theta$, the physical emittance $\varepsilon = \pi^2 (r \theta)^2$, which is in practice the relevant quantity, becomes smaller as the beam is accelerated. The normalized brightness is defined as $B_n = I/\pi^2 \varepsilon_n^2$ and is seen to be none other but the normalized phase space current density. As one intuitively expects, the smaller the beam radius and angular aperture the brighter the beam. More generally, when motions in x and y are uncoupled, the horizontal and vertical normalized emittances, $\beta_\gamma \int z' dz = \pi \varepsilon_{nz}$ (z stands for x or y), are also separately constant. The corresponding normalized brightness value is $B_n = I/\pi^2 (\varepsilon_{nx} \cdot \varepsilon_{ny})$. Here the factor π in the definition of ε_{nz} arises from the beam boundary in two dimensional phase space being an ellipse in the simple case of external forces linear in the particle displacements. For a Gaussian beam with standard deviations $\sigma_z(s)$ and $\sigma'_z(s)$ (z standing for either x or y) the most used expression is $\varepsilon_{nz} = \beta_\gamma \sigma_z \sigma'_z$.

When dealing with non-ideal, irregular beam shapes and current densities, it becomes useful to introduce the *rms* (or *average*) normalized beam emittance $\pi \varepsilon_{nz}^{(rms)}(s) = \sqrt{\langle z^2 \rangle \langle (\beta_\gamma z')^2 \rangle - \langle z \beta_\gamma z' \rangle^2}$, the expression $4\pi \varepsilon_{nz}^{(rms)}$ being used by most authors to define the actual "beam stay clear" envelope in physical transverse space. The corresponding *rms* beam brightness is $B_n^{(rms)} = I/(16\pi^2 \varepsilon_{nx}^{(rms)} \varepsilon_{ny}^{(rms)})$.

Note finally that when in real life one has to deal with nonlinear optical elements and internal forces the *rms* normalized emittances are no longer invariant. They will in general depend on the beam local current density, tending to blow up during beam acceleration and transport and thereby spoiling $B_n^{(rms)}$. A great amount of theoretical and experimental work has and is therefore been devoted to methods and techniques to minimize the final output brightness deterioration particularly of high current sources. Last, keeping the beam energy spread small is also important particularly to reduce chromatic aberrations; the ratio of $B_n^{(rms)}$ to the beam relative momentum (energy) spread $\Delta p/P_0$, called *rms* normalized spectral brightness or brilliance, B_{ns} , quantifies this aspect.

Also note that the brightness is often defined in literature either incorrectly, simply as a current density $B = I/(\Delta S \Delta \Omega)$, or correctly, in normalized form, as $B_{nV} = I/(\Delta S \Delta \Omega V)$, qV being the reference particle kinetic energy. B_{nV} and the adimensional energy dependence definition B_n are related through equation $B_n = (E_0/q) B_{nV}$, with E_0 the particle rest energy.

Electron sources

Electron sources are used to drive a great variety of devices such as power tubes, klystrons, electron microscopes, X rays vacuum tubes and linear accelerators (linacs) for industrial, medical and scientific applications (Gilmour, 2011; Faircloth, 2021). The main objective of an electron source and, more generally, of an electron injector, is therefore to generate an electron beam with a current, longitudinal and transverse particles distribution, and energy, suitable for a specific application.

The general structure of an electron injector is given in Fig. 1, where the three main components are put in evidence: the cathode, the pre-acceleration and beam manipulation systems. The cathode is the source of electrons and can be furthermore divided into three main categories based on the emission mechanism: thermoionic, photo-electric or field emission cathode (Dowell, 2008). Immediately after the source the beam is pre-accelerated by continuous (DC) or radiofrequency (RF) electric fields. The systems composed by the cathode and the pre-acceleration system is usually called electron gun. In the beam manipulation section, electric or magnetic fields are used to make a beam "conditioning" in the transverse and longitudinal planes matching the beam to

Fig. 1 General structure of an electron injector.

subsequent beamline systems or acceleration stages. In particular, in this section, the effects of space charge forces or aberrations have to be properly compensated to avoid degradation of the beam quality.

Time structure of electron beams

The electron beam at the output of a source has the typical beam time structure shown in Fig. 2: the beam is a train of macro-pulses, with duration T_P and repetition frequency $f_{rep} = 1/T_{rep}$. The macro pulse can be a continuous beam or a train of bunches. The second case refers to the RF electron sources and the relatively short bunches have a bunch spacing T_B with a repetition frequency $f_B = 1/T_B$ that is a subharmonic of the RF accelerating field frequency $f_{RF} = 1/T_{RF}$. The ratio $DC = T_P/T_{rep}$ is called Duty Cycle and is typically expressed in percent. Pulsed electron sources have Duty Cycles from a fraction of percent up to several percent, while continuous sources have, by definition, a Duty Cycle equal to 100%. In the case of a RF injector operating continuous mode we usually refer to a CW (Continuous Wave) operation.

Electron guns

An electron gun consists of a cathode, the primary emitter of low energy electrons, and of a system to pre-accelerate the electrons and shape them into a beam. The three fundamental emission processes are: thermoionic emission, photo-electric emission and field emission (Dowell, 2008; Faircloth, 2021).

The electron temperature of the emission process determines the lower limit of the achievable beam emittance that is often called the thermal emittance (or intrinsic emittance), due to the Maxwell-Boltzmann (MB) distribution of thermoionic emitters.

The electron emission process can be understood looking at the behavior of the electric potentials at the cathode surface that is given by three main term: the work function, the image charge potential and the applied electric field as given by the formula:

$$e\phi = e\phi_w - \frac{e^2}{16\pi\epsilon_0 z} - eE_z z$$

Where $e\phi_w$ is the material work function (the minimum energy needed to remove an electron from a solid to a point immediately outside of the solid surface), E_z is the applied electric field and z is the distance from the surface. The graphical representation of the electric potential is given in Fig. 3. Electrons with energies larger than the work function can be emitted, as in the case of thermoionic and photo-emission, while those with lower energy can tunnel through the barrier as in the case of field emission. In this last case if the barrier height is lowered by an external electric field, the process is called Schottky emission.

Thermoionic cathodes

The first way to extract electrons is to heat a material to a high temperature (Herring and Nichols, 1949). When the material is heated, electrons can populate excited states above the Fermi level according to the Fermi-Dirac distribution. Electrons with an energy greater than the Work Function ($e\phi_w$) can escape the surface of the cathode. The thermoionic emission is the resulting flow of electrons extracted from the heated material. The application of a negative voltage helps to extract electrons from the surface (and accelerates them) also providing focusing forces.

Fig. 2 Typical time structure of an electron beam at the output of a source.

Fig. 3 Potential energy barrier near the cathode surface within 10 nm of a metallic surface (right) and density of occupied states (left).

The theoretical maximum extracted current density is given by the Richardson-Dushman equation:

$$J_{RD} = AT^2 e^{\left(-\frac{e\phi_W}{k_B T}\right)}$$

where $A \cong 120 [A/cm^2 K^2]$ is a constant, T is the temperature and $k_B = 8.6 \cdot 10^{-5} [eV/K]$ is the Boltzmann constant. The exponential dependence from the temperature, illustrates how thermoionic current rises rapidly with temperature, and with decreasing work function.

For this reason, cathode material should have relatively low work function and/or high melting temperature. Typical materials are Tungsten ($e\phi_W = 4.53$ eV) that is heated at temperature above 2000 W, or low work function composite, such as LaB₆ crystals that has a lower work function (2.66 eV) and is heated at 1500–2000 K. Typical reachable Richardson-Dushman density currents are $J_{RD} = 10\text{--}100$ A/cm².

Thermoionic guns can be metal filaments (typically W) directly heated with current flowing in the filament itself, or disc-shaped thermoionic emitters with a retro heating system, as given in Fig. 4. Depending on their main application they can be loosely classified into low DC current, high brightness devices, designed for “micro-applications” such as electron microscopy, material analysis and processing, micro lithography, micro machining and medium-high average (DC or pulsed) current sources to drive devices such as klystrons and linacs for scientific and industrial applications.

For the first class of applications currents from nA up to μ A and extremely low emittances are required. Since, for thermoionic cathodes, the thermal contribution to the normalized emittance scales as $\epsilon_{th} \approx \sigma_x \sqrt{k_B T / m_e c^2}$, where σ_x is the rms spot size of the source and T is the cathode absolute temperature, “needle” cathodes are used in combination with DC accelerating system that allows also to collimate, collect and focus the beam (Wehnelt cylinder). The use of high accelerating fields allows also to lower the

Fig. 4 Different types of thermoionic cathodes: (a) W filament for micro applications; (b) diode system for high current devices; (c) triode system for low and medium current sources such as linacs for industrial and scientific applications.

operating temperature due to the Schottky effect, reducing the required working temperature T and making for longer cathode lifetime. Nanometer size spots at the sample can be obtained with very small normalized emittances ($\varepsilon_n \approx 10^{-2} - 10^{-5} \mu\text{m}$) with resulting normalised brightness that exceed $10^{12} \text{A}/(\text{m} \cdot \text{rad})^2$ and energies from a few tens up to few hundreds of keV and energy spread in the 10^{-5} range.

For the second class of applications the cathodes consist of a high melting-point metal disc coated with a low work function material and indirectly heated by a filament. The most used material is Ba or Sr oxide coated tungsten having a work function of $\approx 1.6 \text{ eV}$ and capable of $10 - 20 \text{ A} \cdot \text{cm}^2$ at temperatures of $\approx 1500 \text{ K}$. Because, in the high temperature and high voltage environment the coating tends to be removed rather rapidly by desorption, sputtering and evaporation, dispenser cathodes have been developed made of porous tungsten impregnated with oxide which slowly diffuses towards the cathode surface, continuously replacing the removed material. Operated in good vacuum ($\leq 10^{-7} \text{ hPa}$) a dispenser cathode can typically reach useful lifetimes in the order of 40000 hours. The gun voltage and current specifications vary widely, depending on the application, from the $10 - 100 \text{ kV} / 1 - 10 \text{ A}$ of Linac guns to the $100 - 500 \text{ kV} / 100 - 500 \text{ A}$ of klystron guns. Pulsed beam configurations are obtained by pulsing either the anode voltage (diode configuration) or a grid between the cathode and the anode (triode configuration). The first technique is generally used for high voltage, high current klystrons. In this case, between the cathode and the anode the beam is transversely focused using external solenoids that allow to keep under control the beam emittance increase due to space charge forces. Triode configurations are, indeed, used for low and medium voltage sources such as linacs for industrial and scientific applications. Thermoionic cathodes basically emit a continuous beam that can be modulated by pulsing either the anode or the grid voltage at the level of several ns up to ms level. To allow RF acceleration in the further stages of the linac, the beam has then to be manipulated, as illustrated in the following sections, using special RF cavities that allow to bunch the beam.

For this class of thermoionic guns the self-generated beam field reduces the effective voltage on the cathode, thus limiting the beam intensity with respect to the ideal Richardson-Dushman theoretical value. This regime is called space charge limited Child-Langmuir regime and the maximum current which can be extracted from the cathode can be expressed as: $I = P \cdot V^{3/2}$, being P a constant, characteristic of the device geometry, called perveance. Its measurement unit is the $\text{perv} = \text{A}/\text{V}^{3/2}$ and typical values are few μperv .

Cathode and anode geometries are also designed following the criteria firstly developed by Pierce that proposed to adopt spherical shapes to provide radial focusing forces and increase the beam quality in term of uniformity and emittance (Pierce, 1949). Normalized emittance and brightness values lie typically in the $\varepsilon_n \approx 10^{-3} - 10^{-1} \text{ m}$ and $B_n \approx 10^8 - 10^{11} \text{ A}/(\text{m} \cdot \text{rad})^2$ range respectively.

Photo cathodes

In the photo emission process, the cathode is illuminated by a laser pulse, electrons within the material can absorb the energy of photons and, if this energy is larger than the material work function, the electrons can be ejected (DuBridge, 1933). The photo-electric emission in several material is described by the Spicer's three step model (Spicer, 1958): the photon absorption by the electron, the electron transport to the surface and the escape through the barrier. The model allows to theoretically derive the two main important quantities that characterize a photo-cathode: the quantum efficiency (QE) that is defined as the number of emitted electrons per photon impinging on the cathode, and the normalized intrinsic (or thermal) emittance (ε_{th}) that represents the minimum possible achievable emittance value for a given injector. This second quantity, for a metallic cathode, is given by:

$$\varepsilon_{th} \approx \sigma_x \sqrt{\frac{\hbar\omega - e\phi_{eff}}{3m_e c^2}}$$

where σ_x is the rms laser spot size, $e\phi_{eff}$ is the effective work function and includes the effect of Schottky reduction of the barrier in the presence of an applied electric field (E_x): $e\phi_{eff} = e\phi_w - e\phi_{Schottky} = e\phi_w - e\sqrt{eE_x/4\pi\epsilon_0}$. Photocathode materials can be metal or semiconductors. For a semiconductor cathode $e\phi_w$ in the formula has to be substituted with the sum of the valence-conduction bandgap energy (EG) and electron affinity (EA) (Dowell et al., 2010).

Metal photocathodes (typically Cu, Mg, Nb and Pb) are robust, can operate at relatively high operation pressures ($< 10^{-8} \text{ mbar}$), and due to the high work function, require UV photons ($\sim 250 \text{ nm}$). They typically have QE, in the $10^{-4} - 10^{-5}$ range. An interesting and significant increase in QE occurs when the metal is coated with a few angstroms of CsBr. In this case QE can be enhanced by a factor of 50. The theoretical thermal emittance ($\varepsilon_{th}/\sigma_x$) for metallic cathodes is in the range $0.5 - 1 \mu\text{m}/\text{mm}(\text{rms})$.

Semiconductor cathodes are typically alkali-telluride (as the most common Cs_2Te) or alkali-antimonide materials. They can reach QE larger than 5% and intrinsic emittances comparable with the metallic one but they have to operate at very low pressure ($< 10^{-9} \text{ mbar}$) to avoid deterioration of their performances. Also for these cathodes UV photons are required. Multi-alkali antimonide semiconductors (Na_2KSb or K_2CsSb) show QE larger than 10% but have to operate at extremely low pressure ($< 10^{-10} \text{ mbar}$) to avoid contamination and maintain their performances. The last family of semiconductors is represented by the negative electron affinity (NEA) cathodes (as GaAs) that can operate with longer laser wavelength ($500 - 800 \text{ nm}$) and, illuminated with polarized light, allow for 80–90% polarized beams.

The last key factor of photo-cathodes is the temporal response of photo-emitted electrons with respect to the laser pulse. Metallic cathodes have response time lower than a picosecond while semiconductor typically higher than few picoseconds.

As already pointed out in the previous section, thermoionic cathodes basically emit a continuous beam that can be modulated and properly bunched. On the contrary with photocathodes, the beam micro-structure can be directly generated by modulating the

Fig. 5 Schematic layouts of photo-guns: (a) DC; (b) RF.

drive laser pulse length, shape, spot size, and intensity on a pulse-to-pulse basis. This characteristic allows the generation of short ($< \text{ps}$ for metallic cathodes as example) electron bunches that can be also further compressed in the other stages of the acceleration. This allows to drive free electron laser (FEL) and Compton based sources and to implement techniques such as laser and plasma-wave acceleration for a future generation of compact particle accelerators. For ps bunches with charge larger than few tens of pC, the space charge forces, that scale with the peak current and $1/\gamma^2$, tend to blow out the beam emittance and, for this reason, the beam has to be accelerated to relativistic energies as fast as possible. This is done through DC or RF accelerating fields, as illustrated in Fig. 5. In DC photo-guns the generated electron beam is accelerated by static electric field between the photo-cathode and the anode. Voltages in the 100–400 kV range and accelerating field lower than 10 MV/m are typically implemented. Larger voltages cannot be applied because of the risk of electric-field breakdown in the vacuum chamber. This limits the maximum performances in term of achievable peak current and charge density, related to the reachable cathode peak field, but allow operation at very high Duty Cycle up to CW. In room temperature RF guns the cathode is integrated in an accelerating cavity with oscillating electromagnetic fields (Rao and Dowell, 2014). They typically operate in S band (3 GHz) in pulsed regime with Duty Cycle less than 1% and cathode peak field in the range of 100 MV/m with output energies of several MeV (Alesini et al., 2018). L band (1 GHz) guns with cathode peak field < 60 MV/m have been developed for high Duty Cycle ($> 1\%$) accelerators (Dwersteg et al., 1997). RF guns operating at lower frequency (VHF Band, ~ 200 MHz) have been also design and implemented for CW operation because of the larger sustainable average dissipated power with ~ 20 MV/m cathode peak field and output energies ~ 1 MeV (Sannibale et al., 2012).

In high Duty Cycle guns (DC or RF), cathodes are semiconductor because of the lower average energy required for the laser system impinging the cathode itself (Smolenski et al., 2009; Gulliford et al., 2013). This requires an extremely good vacuum performances and operating pressure to guarantee the cathode lifetime (Musumeci et al., 2018).

A strong R&D activity is now in progress in several laboratories and is related to the development of superconducting RF guns (Arnold and Teichert, 2011; Petrushina et al., 2020). The potentialities of these type of guns are related to the fact that they can, in principle, operate with high cathode peak fields, in CW mode, with cathode peak field larger than 100 MV/m, but there are limitations due to the applicable magnetic field (necessary for beam emittance compensation processes) and insertion of photo-cathodes in a superconducting operating system.

High cathode peak field guns (> 80 – 100 MV/m) have also to cope with the charge emitted by field emission and called “dark current” because is emitted from the cathode surface and cavity wall even without laser (Shu et al., 2021). This current is emitted in the negative RF half-wave in all RF periods and can drive a total charge in the RF pulse that superimposed to the photo-emitted bunch current. Cleaning procedures and surface treatments have to be implemented in order reduce this dark current thus avoiding activation of components, damages of instrumentation and background for experiments.

Field emission cathodes

Field emission (FE) occurs under the influence of very high electric field at the level of 10^7 – 10^9 V/m (Murphy and Good, 1956). Under the effect of such high electric field, electrons near the Fermi level quantum mechanically tunnel through the barrier and useful emission currents can be achieved. The Fowler-Nordheim theory describes this process. Because of the relatively low current but extremely high reachable brightness, they are used, typically, as source of ultra-high resolution scanning (transmission) electron microscopes (S(T)EM) (Krysztuf, 2021).

A field emission cathode is, typically, a tungsten needle with radius smaller than 100 nm settled on a Tungsten hook with a negative bias voltage of several kV applied to the cathode and electric fields that can overcome the 10^9 V/m values. With these sources, it is possible to obtain a current density of 10^5 A/cm² (that is orders of magnitude larger than that of a thermoionic emission).

FE guns can be Cold Field Emitters (CFE), Thermal Field Emitters (TFE), Schottky Field Emitters (SFE). In CFE the emission derives from a few nanometers area and it is independent from the source temperature. The beam is focused and accelerated by two anodes with a bias voltage of few 3–5 kV. A bias voltage of several tens of kVs between the second anode and the cathode accelerates the electrons at the required energy. Even if the total current is relatively small (1–10 μA), the brightness is particularly high ($>10^{12} \text{ A}/(\text{mmrad})^2$) thanks to the very small beam dimensions at the source and the beam dimensions at the sample can reach the nm level. TFE have the same properties of CFE, but they work at high temperatures thus reducing the noise and beam instabilities even at not perfect vacuum conditions. In SFE field emitters are coated with low working function materials such as ZrO_2 and the thermoionic emission is combined with field emission. Vacuum level is not as demanding as that one of CFE, but an ultrahigh vacuum allow for long-term stability, preventing poisoning of the ZrO_2 cathode. The larger source spot size in SFE is compensated by larger currents that can exceed the 50 μA level thus reaching comparable brightness.

Beam manipulation systems

After the guns, the emitted beam is focused and bunched to allow applications or further stages of acceleration. We can refer to these systems as beam manipulation devices. They have different configurations depending on the cathode type and applications.

In thermoionic guns used as sources of low energy ($<10 \text{ MeV}$) industrial linacs, the continuous beam at few tens of keV, is directly injected in radiofrequency accelerating structures that have the first accelerating cells designed in order to capture a large fraction of the continuous beam current, allowing, also, bunching, as illustrated in Fig. 6a. For this reason this part of the linac is called “buncher.” The bunching cells can be either integrated or separated with respect to the other stages of acceleration (Kutsaev, 2021). Typical few μs continuous beams at a repetition rate of few hundred Hz, are bunched in a microstructure having a bunch distance equal to the rf period used for the other stages of acceleration (typically 0.1–0.3 ns for operation in S and C Band). This relatively simple scheme allows to obtain capture efficiencies up to 40–50% with energy spreads of several percent and long bunch tails that are generated in the bunching process.

To improve the beam quality in term of bunch length and energy spread, “pre-bunchers” can be also adopted, as schematically illustrated in Fig. 6b. This is the case of high energy linacs used for scientific applications for which thermoionic gridded cathodes are used at voltages in the 100–200 kV range. Pre-bunchers are standing wave RF structures that modulate the energy of the continuous beam out from the gun. The energy modulation results in a velocity modulation and, after a drift space, in a density modulation, allowing a better capture of the beam. Other techniques implement choppers that are RF deflecting cavities sweeping, transversely, the continuous beam. The swept beam is then collimated and a microstructure with extremely good beam quality, in term bunch tails and energy spread, can be achieved.

The typical beam parameters, in term of emittances (in the range 0.1–1 μm), bunch length (several tens of ps with relatively long tails) and energy spread 1–5% that can be obtained in thermoionic-based linacs are not compatible with scientific applications that require extremely good beam performances. We refer, in particular, to linacs for FEL and high brilliance Compton sources where normalized emittances lower than 1 μm , energy spread of $<0.1\%$, and bunch length $<1 \text{ ps}$ with peak bunch current of few kA are required.

Fig. 6 Schemes of thermoionic based injectors for low energy industrial linacs (a) and high energy, high beam quality linacs for scientific applications (b).

Fig. 7 Conceptual layout of an RF photo-injector with velocity bunching.

To reach these parameters RF photo-guns are typically used. A laser pulse, of a suitable wavelength, extracts the electrons from the cathode, embedded in the cavity. An external RF power source (klystron) excites the cavity accelerating mode so that the photo-electrons are immediately accelerated by the RF electric field on the cathode and all along the gun beam axis. Under the combined action of the RF accelerating field and of an external focusing solenoidal magnetic field, the dynamics of the electron beam, that has a typical charge of 0.1–1 nC, is guided and controlled and the effects of space charge, properly compensated (Serafini and Rosenzweig, 1997). The conceptual scheme is reported in Fig. 7.

Presently, the RF technology mostly used for RF Guns is the S-band (3 GHz). The S-band is used in particular, for facilities operating at low rep rate ($\text{frep} \leq \sim 100$ Hz) low duty cycle ($<0.1\%$) single bunch, while lower frequency technologies (L-band, VHF) are used for higher rep rates and multi bunch linacs. According to beam dynamics studies, the higher the peak electric field on the cathode, the better the quality of the beam emerging from the gun. In this respect the S-band represents the state-of-the-art, providing typical peak fields of ≈ 120 MV/m on the cathode. Even though larger values would be very much desirable to further improve the beam quality, it was found experimentally to be very difficult to go beyond 120 MV/m in S-band based injectors. The limitation comes from the unacceptable increase of the RF breakdown rate (BDR) that is a complex phenomenon which depends on many aspects, such as conditioning time and strategy, construction quality, surface cleanliness, residual pressure. Synchronization systems have, also, to be carefully implemented to avoid jitters between the laser and the RF that results in unstable operation and oscillations in the beam parameters. Typical energies out from RF photo-guns are in the range 1–7 MeV with normalized emittances in the range 1–2 μm , bunch length of few ps and peak bunch currents <100 A. In the case of multi bunch operation or high Duty Cycle facilities as, for example, the injectors for the energy recovery linacs, also DC photo-gun are used. As already pointed out, in this case, the cathode peak field cannot reach the value of RF photo-injectors and the extracted charge has to be reduced to avoid emittance increase due to space charge.

To further increase the bunch peak current after the rf gun, the longitudinal phase space can be manipulated. There are basically three techniques that can be used to this purpose: velocity bunching, ballistic bunching (Anderson et al., 2005) and magnetic compression (Di Mitri, 2018). In the first case the few MeV bunch is injected in an RF accelerating structure off-crest (typically at the zero crossing of the RF accelerating field) so that the head and tail are accelerated all along the structure with an head-tail different energy gain that results in a velocity modulation and a consequent reduction of the bunch length. The emittance is kept under control by adding focusing solenoids around the accelerating sections. Fig. 7 reports this scheme of compression. The ballistic bunching mechanism works similarly but with a single standing wave cavity that kick the head and tail of the bunch immediately after the gun. This kick is converted into density modulation after a drift space as in the case of pre-buncher cavities for thermoionic guns. In the magnetic compression the bunch receives a head-tail energy chirp in the acceleration process and a magnetic chicane transforms this energy chirp in longitudinal particle position variation thus allowing compression. The first two methods typically work at output energies from the gun of few MeV while the third one at energies above the 100 MeV level.

Frontiers in electron sources development

Frontiers in the research of electron guns include new types of RF injectors operating at very high cathode peak field (>150 – 200 MV/m) and high RF frequency (C band, 6 GHz), that allow to obtain extremely high-brightness beams with repetition rates up to 1 kHz (Alesini et al., 2022). Other schemes are exploring the possibility to integrate field emission cathodes (as carbon nanotubes) in RF guns avoiding the use of lasers or thermoionic processes (Faillace, 2015). The R&D activity involves also plasma

gun based on laser driven plasma wake accelerators to be capable of GV/m electric fields, micrometer spot sizes, and femtosecond-long bunches. The schemes foresee a high intensity laser pulse that, injected in a gas (H₂ as example) ionizes the gas itself thus creating an accelerating plasma wave able to directly generate and accelerate ~ 100 fs, < 0.1 nC bunches with peak currents up to the kA. The technology research is also oriented to realizations of superconducting guns that, as already pointed out, allow to simultaneously achieve CW operation and extremely high cathode peak field.

Positron sources

At present, positrons beams are used in different fields and applications. At non relativistic energy (thermal sources) they can be very effective as probe for defect spectroscopy and detection in metals, semiconductors and isolators (Giley et al., 2006). In this framework the very high sensitivity is given by the attractive potential of the negative charged impurities. Slow positrons are also used for experimental activities in the field of electron-positrons plasmas, Positronium (Ps) decay and spectroscopy, Ps₂ molecule formation, Positron Annihilation induced Auger spectroscopy (PAES), Bose Einstein condensate and gamma ray production (gamma ray laser) thanks to the e^+e^- 0.511 keV annihilation line at rest (Dupasquier et al., 2009). In the relativistic and ultra-relativistic regimes positrons beams are used in the framework of the high energy physics positrons-electrons (e^+e^-) colliders. In this context leptons are particularly suited for the reduced background noise in respect to hadron colliders. Moreover e^+e^- very high luminosity colliders are used to explore the intensity frontier in fundamental particle physics (Chaikovska et al., 2022). In the past, thanks to the suppression of the positive ions instability positrons had also be used in storage rings as synchrotron radiation sources, where a positron source was available (Besson et al., 1989).

Slow positrons

Slow positrons are usually produced by radioactive sources. As far as the positrons are concerned, the efficient process is the β^+ decay (Chehab, 1989) that, taking into account the conservation of charge, can be considered as the decay of a nucleus proton in a neutron with the emission of a positron and an electron neutrino:

resulting in a reaction in which an atomic nucleus decreases by one his atomic number:

Since the neutron mass is ~ 1 MeV bigger than the proton mass, this reaction is forbidden for isolate protons. The proton decay can be seen only in the nucleus, where the final daughter state has respectively greater binding and lower total energy in respect to the mother state. In this framework the total energy released in the β^+ decay must be higher than twice the electron mass,

$$Q = m({}_Z X) - m({}_{Z+1} X) - 2m_e$$

where m and m_e are respectively the mass of the generic atomic nucleus X and of the electron e , and Z is the nucleus atomic number. Typical positron emission spectrum is asymmetric bell shaped (see Fig. 8) with energies that typically go up to one MeV and large energy spread of hundreds of keV. Due to the handling requirements of radioactive sources usually long half time isotopes are

Fig. 8 Typical spectral distribution of positrons emitted by beta decay.

preferred like ^{22}Na (2.6 years) and ^{58}Co (71 days). ^{22}Na sources emission also presents a good positron emission efficiency resulting in the primary technique for producing low energy positrons by radioactive beta decays. Available sources give a maximum activity in the order of some GBq, from one to four.

Nuclear reactors can also be used to trigger p-n or n- γ reactions to produce positrons emitting isotopes (Ottewitte, 1987). Thanks to the high neutron flux it is possible to have typical reactions like

followed by the decay

A typical example is the reaction ${}^{63}\text{Cu} + n \rightarrow {}^{64}\text{Cu} + \gamma_{\text{ph}}$ decaying in ${}^{64}\text{Cu} \rightarrow {}^{64}\text{Ni} + \beta^+ + \nu$. Other suitable positrons beams producing isotopes are, for example, ${}^{83}\text{Sr}$, ${}^{76}\text{Br}$, ${}^{72}\text{As}$, ${}^{84}\text{Rb}$, ${}^{26}\text{Al}$ and others, with different characteristics decay time, positron producing efficiency and reaction products.

Also p-n reactions can trigger positron production via some characteristics decay like:

followed by

like for example:

In this framework the total rate of positron production is given by:

$$\frac{dN_{e^+}}{dt} = B \sigma \varphi V N$$

Where B is the β^+ branching ratio in respect to the disintegration events, σ is the positrons production cross section (for example in the reaction $p + {}^{17}\text{O} \rightarrow {}^{17}\text{F} + n$; ${}^{17}\text{F} \rightarrow {}^{17}\text{O} + e^+$ its value is ~ 200 mb), φ is the thermal neutron flux, V the target volume and N its atom density. Thanks to the huge thermal neutron flux present in the nuclear reactors it is possible to increase the positron rate of orders of magnitude. Nevertheless, the difficulty in accessing nuclear plants in respect to a radioactive source is a basic limitation for this production scheme.

Moderation

All sources mentioned emit slow positrons isotropically and distributed in a large energy spectrum. Since all the applications require quasi monochromatic beams (and with a good directivity) it is possible either to have a spectrometer energy selection or to cool the emitted positrons in a thermal positron cloud that can be re-accelerated a posteriori by an applied electrostatic or electromagnetic field. The spectrometric selection is a classical and reliable scheme, but it suffers from a very poor efficiency due to the losses in the angle-energy selection. On the other side, it is possible to decrease the positron energy by introducing a solid or gaseous moderator with higher efficiency $\xi = N_{e^+, \text{slow positron available}} / N_{e^+, \text{fast positron emitted}}$. The cooling in gas is basically given by the positron energy loss due to molecular rotational and vibrational excitation. Appropriate gases are chosen so that positron annihilation cross section is low in a selected energy range. On the other side, the energy range in which these cross sections are high is fast passed due to the high probability for appropriate inelastic scattering processes. For example, the annihilation process like the positronium formation has a threshold at 8.5 eV, above this threshold thermal cooling is very effective due to rotational and vibrational excitations, thus reducing the positronium formation with the consequent positron annihilation. Below the threshold the positrons gas continues to cool thanks to the molecular interactions. Due to the high excitations cross sections mixtures of SF_6 , CF_4 and CO_2 gases with N_2 are often employed as gas moderators.

The cooling in solid is mainly given by a first energy loss due to multiple inelastic scattering in the material bulk. After thermalization there is a finite probability for them to diffuse to the solid surface. When the solid has a negative work function for the positrons, they can be emitted perpendicularly with a spectrum peaked around the corresponding positron work function. The process efficiency is mainly limited by the backscattering reflection in the solid or by the positron loss processes like annihilation with bulk electrons or positronium formation. Typical solid moderators are realized in Tungsten (W with efficiency of 10^{-4} with a 0.3 eV energy distribution) or Nickel (Ni). With the techniques of solid rare-gas moderators, obtained by freezing Neon gas onto a metal surface at cryogenic temperature (8 K) (Mills and Gullikson, 1986), it is possible to increase the moderator efficiency to $\xi = 10^{-2}$. To increase the emission in a given direction it is also possible to integrate the radioactive source in systems made of a high Z reflection material to enhance the directivity of the emitted flux. A typical example, with the source integrated in the front of a tungsten support, is illustrated in Fig. 9.

The total efficiency of the moderator process gives the final available slow positrons flux, which, for radioactive sources, can go up to 10^6 e^+ /s whereas it can achieve 10^8 – 10^9 useful e^+ /s for the reactors isotopes.

Fig. 9 Possible configuration β^+ source—W reflector to increase the source available flux.

To create at rest positron plasma (Jørgensen et al., 2005), buffer gas moderation can be inserted in a series of electrostatic electrodes with applied potential providing a longitudinal confinement and surrounded by a solenoidal field for the transverse one. After a first cooling phase the gas is extracted and the positrons are further respectively cooled and compressed by emitting photons by cyclotron radiation in the solenoidal field and by an applied torque given by a sinusoidal electric field imposed on splitted electrodes (rotating wall technique) (Danielson et al., 2006). At the end the cold positron plasma can be extracted by kicking the electrostatic potential of the last electrode. With this technique it was possible to merge cold positrons and antiprotons producing the first anti Hydrogen atoms at cryogenic temperature.

Photoproduction

As far as high relativistic and high intensity positron beams are concerned, their production is provided by the conversion of gamma rays, with energy higher than the electron-positron mass threshold $E > 1.022$ MeV, in the nuclear potential of the atoms of a target. The “primary” beam electrons interact with the target nucleus and they produce a high flux of soft and hard gamma rays by bremsstrahlung. These are subsequently converted in e^+e^- pairs by the process $\gamma_{ph} + A \rightarrow A' + e^- + e^+$ with a cross section, similar to the bremsstrahlung one (Donahue, 1991) directly proportional to the square of the classical electron radius r_e and of the atomic number Z of the material and to a “screening effect” complex function $F(\gamma_{ph}, Z)$. This is known as the Bethe-Heitler process, to be distinguished from the trident process where the pair production takes place directly in the nucleus ($e \rightarrow e^- + e^- + e^+$), triggered by the electron coulomb field. Also in this case the cross section is proportional to the square of r_e and Z and to a complex function of γ . Usually the primary beam has energies in the range of 150–300 MeV with $0.3\text{--}3 \cdot 10^{10}$ electrons per bunch, but in a high energy laboratory the positron production has also been performed at 3.7 and 33 GeV (Variola, 2014).

The mean free path for a high energy photon to convert in one pair in a solid is given by $(7/9) X_0$ where X_0 is the characteristic radiation length of the material (Tanabashi et al., 2018). The produced pairs immediately start to contribute to the γ_{ph} production with consequent other pairs conversions triggering the development of an electromagnetic shower with typical production yield in the order of few % GeV^{-1} . On the other side, low energy positrons lose their energy by ionization thermalizing in the material so contributing to the average heating. The equilibrium between cascade production and energy losses gives an optimized target length for the positron production around $3X_0$ for a primary beam of 1 GeV and it scales approximately as $\ln[\gamma]$. The target has to be designed to withstand both the average thermal stress and the high thermo-mechanical stress given by the temperature derivative in the target, expressed by the Peak Energy Deposition Density (PEDD), so avoiding the target failure. Typical melting temperature are 1940° for Ti, 3695° for W and 3460° for Re. PEDD threshold is given by experiments, a typical value shows 35 J/g for a $6X_0$ $W^{25}\text{Re}$ target (Bharadwaj et al., 2001). Due to the high melting point often ^{74}W , $^{76}\text{W}^{24}\text{Re}$ but also Ta have been preferred for positron sources (Chaikovska et al., 2022). To reduce the thermal deposition different design have been proposed like wire targets and granular targets based on 2 mm W spheres. When the thermal load is unsustainable by solid target different solutions have also been introduced, like liquid lead or $\text{Ti}^6\text{Al}^4\text{V}$ rotating targets. In the last case the choice of Ti targets are justified by the reduced activation issues in low Z materials.

Positron capture

Energy losses and multiple scattering result in a loss of “memory” of the phase space characteristic of the primary beam providing high values of the 6D emittance of the final e^+ beam. To avoid very important losses at the source it is therefore mandatory to immediately insert a focusing system reducing the angular spread to the detriment of the geometrical size. This system is based on a decreasing solenoidal B field with high initial peak values at the target (up to 10 T) reduced to a constant value (typical value

between 0.25 and 0.5 T). If this field reduction is adiabatic the system is called Adiabatic Matching Device, if the transition is abrupt it is known as Quarter Wave Transformer (QWT). Angular and radial acceptance of these systems is function of the peak and lower field, of the particle momenta and of the geometrical system aperture (Chehab, 1989):

QWT

$$R = \frac{2\pi^2}{3} \left(\frac{eB_2 a}{2} \right)^2 \left(1 - \left(1 - \frac{1}{\sin^2 \chi + \left(\frac{B_1}{B_2} \right)^2 \cos^2 \chi} \right)^{\frac{3}{2}} \right); A = \frac{eB_1 a}{2P} \left(1 + \frac{B_2}{B_1} \right)$$

AMD

$$R = \frac{2\pi^2}{3} \left(\frac{eB_2 a}{2} \right)^2; A = \frac{e\sqrt{B_1 B_2}}{P} a$$

Where R and A are the radial and the angular acceptance, B_1 and B_2 are respectively the maximum and the minimum magnetic field, a is the accelerating section iris radius (geometrical acceptance), P is the scalar momentum and χ is the rotation Larmor angle

$$\chi = \int \frac{eB}{2P} dz$$

Other focusing systems are based on Lithium lenses providing a very high B field azimuthal field at the target location. The focal strength is mainly limited by the maximum achievable current in the lens. The other technical limitation is given by the compatibility of lithium lenses in an ultrahigh vacuum environment.

After the transverse compression the longitudinal one is performed by a series of accelerating sections (longitudinal lenses) enclosed by solenoids providing the constant low B field to avoid positron losses due to the high divergence of the positron beam. Different RF longitudinal compression schemes are possible starting the positron capture in either accelerating or decelerating phase. At the end of the longitudinal and transverse positron capture typical positron fluxes range from 10^{10} to 10^{12} e^+/s .

Photon production separation

To further reduce the thermal deposition in the target the photon-primary electron beam separation is introduced in the positron source design. Taking into account a separated gamma source, with a consequent conversion of only the produced gamma rays beam, this excludes the heating given by the primary beam energy losses in the target. The basic scheme is illustrated in Fig. 10.

In this framework different schemes are taken into account. The first considers a very high energy primary beam injected in a helical undulator channel with a variable K (function of energy). This scheme allows the production of a large amount of gammas per primary electron bunch and at the same time provides photon circular polarization that will subsequently be transferred to the positron helicity. The main drawback is that to obtain the proper gamma energy for positron production it is mandatory to provide a very high energy primary beam (in the order of few hundreds GeV) (Adolphsen et al., 2013).

To reduce the primary beam energy to some GeV, another scheme takes into account the production of high energy gamma rays by Compton backscattering in dedicated facilities (Omori et al., 2006). High density electron beam collides with high intensity laser pulses resulting in a beam of backscattered gammas. Depending on the required photon energy it is possible to tune the frequency of the impinging lasers. Typical wavelengths are 515, 800 and 1030 nm. This solution has the advantage of the tunability and the polarization selection. The drawback is the low flux given by the Compton cross section resulting in less efficient positrons production.

Another explored configuration is given by the production of a "soft" gamma ray spectrum by channeling emission in a oriented crystal (Artru et al., 2005). The primary beam is sent to a crystal (typically W, Ge or Si) aligned on the $\langle 111 \rangle$, or the $\langle 110 \rangle$ axis. If the angle of incidence is lower than a characteristic critical angle $\theta_c = \sqrt{\frac{2V}{E}}$ with E the beam energy and V the potential given by the

Fig. 10 The photon flux separation scheme is illustrated. The primary beam, after the emission of the gamma rays in the radiator, is discarded to a dump by a deflecting dipole. Only the produced gammas are subsequently converted in pairs.

atomic rows in the crystal, the particles undergoes a motion and a radiation emission similar to the wiggler one with periods of the order of several atomic separation distances. This scheme strongly enhances the production (factor ~ 5) in the soft part of the gammas spectrum in respect to the bremsstrahlung one. This allows a more efficient positron production in the energy range suitable for conversion and post capturing by the capture system. In this configuration it is not possible to provide polarized positrons.

Low intensity beams of polarized positrons are also obtainable by polarized bremsstrahlung, where the “classical” production scheme is performed with polarized electrons. Only selecting a small part of the produced positrons energy spectrum results in a good polarization degree, therefore reducing the achievable maximum current.

Generation by lasers

The increased capability of lasers system to deliver very short pulse length and higher peak power and intensity also opens the way to a new scheme of positron generation (Sarri et al., 2022). When a pulse of high intensity impinges on a solid target the electrons are accelerated in the very intense field and their quivering results in an acquired energy of:

$$E = m_e \left[1 + \left(\frac{eE_L}{m_e \omega_L} \right) \right]$$

Where m_e is the electron mass and ω_L and E_L are respectively the laser frequency and field. For a 10^{20} W/cm² class laser the electrons are accelerated up to energy of few MeV, sufficient for pairs’ conversion in the target nuclei. This can be done through the two main primary processes respectively the Bethe-Heitler or the Trident one. The former dominates for thick high Z radiators, the latter for thin target (for example less than 30 μ m for a gold foil). Promising experiments show that for a $120 \text{ J} - 6 \cdot 10^{19} \text{ W/cm}^2$ laser on targets, a production of $2 \cdot 10^{10} \text{ e}^+/\text{sr}$ was obtained with a positron population peak energy of 4–7 MeV and a spread of $\sim$ some tenths %.

More ambitious is the direct production of pairs in vacuum where the laser field must exceed the Schwinger critical field, 10^{28} W/cm^2 . This is not achievable at the present status of technology, but production of high energy and highly collimated positron pairs have been produced in laser assisted experiments. In this experiment a “drive” 29.2 GeV electron beam undergoes Compton backscattering in an intense 0.6 J–527 nm laser field (Burke et al., 1997). The produced high energy gamma ray triggered the Breit-Wheeler process $\gamma_{ph} + \gamma_{ph} \rightarrow e^+ + e^-$ in its nonlinear form $\gamma_{ph} + n\omega_L \rightarrow e^+ + e^-$ (with ω_L = laser photon energy), interacting with many photons of the laser field. In this framework a low positron number per collision was produced (about 100). For a higher flux to be achieved for this very high brilliance source, a Lorentz parameter $\eta > 1$ (where the single Compton backscattering events become a coherent emission) and the Schwinger threshold with the laser need to be attained. In this scenario the emitted photon is fully in quantum regime (energy bigger than m_e) and there is an exponential increase of the emitted γ to the laser field interaction probability for positron emission.

Conclusion

Nowadays electron and positron sources provide high quality particle beams to different users communities. Their main quality parameters are represented by the beam emittance and brightness taking into account the occupied phase space and the beam intensity. Electrons are present in nature, their sources are based on emission mechanisms. On the other side positron sources needs either radioactive decay processes or secondary beams production, either by primary electron or photons beams. This makes electron source much more diffuse thanks also to their relative reduced costs. Electrons are also, at present, the most used particles for the generation of photons beams for the applied science, like in Synchrotron and Compton sources. At present many applications indicates the needs to conceive sources providing high average current but maintaining good values of the emittance. This requires not only in maximizing the production rates but also in providing more and more efficient beam manipulation systems, able to collect, shape and accelerate the produced beams.

Abstract

A review of the four fundamental laws of thermodynamics is provided, together with an extension to anisotropic media. The role of surroundings in systematizing heat and work transfers is emphasized.

Key points

- Generation of a universal temperature scale
- The Zeroth law of thermodynamics
- Definition of Heat and Work
- Ramifications of the first law of thermodynamics
- Definition of entropy and the second law of thermodynamics
- The Clausius inequality
- Efficiencies of operation of cyclic engines
- Use of deficit functions
- Functions of state under various operating conditions
- Maxwell relations
- Cross derivatives and their use
- The third law of thermodynamics, nonachievement of zero temperature
- Properties of anisotropic media
- Effect of surroundings on properties of materials

Introduction

A general overview of thermodynamic principles is provided herein, with emphasis on topics that are useful in dealing with materials properties. The theory is extended to deal with anisotropic media. Thermodynamic operations are elucidated by considering the effects of surroundings, thereby eliminating the standard inequalities that are in common use.

The zeroth law, temperature, and equations of state

The venerable field of thermodynamics rests on four basic laws that are discussed in turn.

The zeroth law asserts that “two bodies in equilibrium with a third are in equilibrium with each other.” This seemingly obvious statement of transitive properties has important ramifications: consider systems 1 and 2 surrounded by walls that effectively isolate

them from the rest of the universe, but allow them to be independently subject to mechanical deformations via pressures P_1 and P_2 (forces per unit area) that deform their volumes V_1 and V_2 . While the systems are separated, these four quantities may be varied independently. However, when joined together and allowed to equilibrate, it is an experience of mankind that only three of the four variables may be independently altered. This is expressed mathematically by the relation $\beta_3(P_1, V_1, P_2, V_2) = 0$. Repeat the process for systems 1 and 3, leading to the expression $\beta_2(P_1, V_1, P_3, V_3) = 0$. Then by the zeroth law, $\beta_1(P_2, V_2, P_3, V_3) = 0$ on combining systems 2 and 3. As long as mutual equilibrium prevails after each combination, system 3 remains unaltered in its union with either system 1 or 2; one can then solve for P_3 in the functions β_2 and β_1 to express $P_3 = \Phi_1(P_2, V_2, V_3) = \Phi_2(P_1, V_1, V_3)$, from which the following difference function is constructed: $\Phi_1(P_2, V_2, V_3) - \Phi_2(P_1, V_1, V_3) \equiv \lambda(P_1, V_1, P_2, V_2; V_3) = 0$. Unfortunately, a glaring inconsistency now emerges: the functional dependence of λ on V_3 is absent from the function $\beta_3 = 0$; also, it makes no sense to refer to λ in system 3 when combining systems 1 and 2. To resolve this impasse, let V_3 occur in Φ_1 and Φ_2 so as to cancel out when their difference is constructed. This may be achieved in most general terms by writing $\Phi_1 = f_2(P_2, V_2)h(V_3) + q(V_3)$ and $\Phi_2 = f_1(P_1, V_1)h(V_3) + q(V_3)$, where h and q are arbitrary functions of V_3 . Substitution of the last two equations in the function λ then leads to the relation

$$f_1(P_1, V_1) = f_2(P_2, V_2) \quad (1a)$$

Similarly, consistent with the zeroth law,

$$f_1(P_1, V_1) = f_3(P_3, V_3) \quad (1b)$$

Reference is now made only to the variables appropriate to each separate system. Eqs. (1a), (1b) thus characterize the equilibration process, and they permit one to consider system 1 as a reference standard that determines whether systems 2 and 3 are in equilibrium, according as system 1 is or is not changed when it comes successively in contact with systems 2 and 3. Clearly, the functional interrelation specified by $f_1(P_1, V_1)$ is of great significance; therefore, a short-hand notation symbol τ_1 , termed the “empirical temperature function” is provided for this function. The relationship $\tau_i = f_i(P_i, V_i)$ is known as an “equation of state” for system i . One can thus characterize the empirical temperature of a given system through measurements of its pressure and/or volume. While it has been worked here with mechanical variables, other experimental measurements could have been used in a similar fashion to construct empirical temperatures. Many different methods for monitoring temperature have been employed; these are described in review articles on the subject. Only the use of a gas thermometer is briefly discussed here. Other commonly used techniques include measurements of electrical resistivity, thermocouple voltages, paramagnetic susceptibility, pyrometers, and thermal expansion; a description of these and other techniques would be beyond the confines of this article.

The labeling of τ_i as “temperature” obviously introduces a link between physical properties and human sensory perceptions of “hotness levels.” The ordering of different hotness levels requires a quantification scheme via an empirical temperature scale; one may employ the equation of state of any suitable material as one indicator of hotness; an enormous multitude of other indicators has been applied for the same purpose. For present purposes, Boyle’s law $f(P, V) = PV = \text{constant} \equiv \tau$ is adopted, which applies to an ideal gas, such as He at low pressure and at a constant temperature well above its critical point. The PV product can then be used as a measure of hotness. A useful quantification scheme is the so-called “Celsius” scale that assigns the values $\tau = 0^\circ\text{C}$ (the original intent, but nowadays assigned a value 0.01°C) and $\tau = 100^\circ\text{C}$ to water that is equilibrated, respectively, with ice and with steam at 1 bar. Let V_0 , and V_{100} be the volume of He gas at a fixed, low pressure and at temperatures τ , 0°C and 100°C respectively; then τ is specified by

$$\begin{aligned} \tau = 100(V - V_0)/(V_{100} - V_0) &= 100 V/(V_{100} - V_0) \\ &- 100 V_0/(V_{100} - V_0) \equiv T + T_0 \end{aligned} \quad (2)$$

A straight line plot of τ versus V based on the above two assigned points extrapolates to an intercept $T_0 \equiv -100V_0/(V_{100} - V_0)$ which has been found to have the value -273.15°C , where the volume V of the ideal gas would vanish, if the gas could be maintained at lowest temperatures. (Actually, the third law, discussed below, shows that a perfect gas cannot exist at very low temperatures. This, however, does not prevent introducing the ideal gas concept as an excellent approximation to properties of a real gas, and then extrapolating its characteristics to the ultralow temperature range, showing what its properties would be if the gas could be maintained in that range. The extrapolation to $V = 0$ suggests that there exists a natural lower limit to the hotness levels, and that an absolute temperature scale may be set up by adding 273.15 to the Celsius scale. One thereby establishes the “thermodynamic temperature scale” $T(\text{K}) = \tau(^{\circ}\text{C}) + 273.15$.

Force, heat, work, and the First Law of Thermodynamics

In preparation for the next step, let x_i represent a “deformation or thermodynamic coordinate” (such as volume, pressure, temperature, mole number, and the like) that characterizes the thermodynamic state of a given system, and let f_i represent any causative agent by which this particular state may be altered; this is taken to be the “thermodynamic force.” Then, the element of work of type i performed “on a system” by its surroundings is specified by $f_i dx_i$; if more than one force brings about a change in x_i , the various contributions must be summed. f_i must remain sufficiently small so as to avoid turbulent or dissipative effects, otherwise, a whole host of extrathermodynamic variables would be required to characterize the process. One thus deals with reversible processes that involve only infinitesimal displacements of a system from equilibrium. Also, the force itself may depend on the displacement and may or may not be collinear with the deformation coordinate. These situations are addressed by expressing

the work performed on the system when changing its state from x_1 to x_2 as $W_i = \int_{x_1}^{x_2} f_i(x_i) \cdot dx_i$, where the force is taken to be a vector and the dot vector product has been introduced. In general, such a line integral depends on the chosen path that takes the system from state x_1 to x_2 , whence this is also the case for the differential quantity $dW = f_i(x_i) \cdot dx_i$. To emphasize this point, the special symbol δ has been used. It is obviously awkward to have to deal with path-dependent entities; hence, one searches for functions that depend only on the initial and final states of a given process; such entities are known as "functions of state." In the present example, a path-independent work performance may be generated if the force is representable as the gradient of a potential, so that $f = -\nabla \phi$, whence

$$\begin{aligned} -W_i &= -\int_{x_1}^{x_2} f_i(x_i) \cdot dx_i \\ &= \int_{x_1}^{x_2} \nabla \phi \cdot dx_i = \phi(x_2) - \phi(x_1) \end{aligned}$$

is indeed seen to depend only on the initial and final values of ϕ . The presence of the minus sign indicates that in going from a higher potential $\phi(x_2)$ to a lower potential $\phi(x_1)$, the system does work on the surroundings, the negative of work done by the surroundings on the system.

Mathematical formulations of commonly encountered types of work are briefly listed, but the list is not exhaustive: (1) mechanical pressure – volume work: $\delta W = -P dV$; (2) enlargement of surface area A : $\delta W = -\sigma dA$, where σ is the surface tension; (3) gravitational work involved in lifting mass $M dn$ (M is the gram-molecular mass and n is the mole number) through a height z : $dW = gzM dn$, where g is the gravitational constant; (4) electrostatic work (in Gaussian units): $\delta W = \int d^3r E \cdot \frac{dD}{4\pi} = -\int_V d^3r P \cdot dE_0$, where E , D , P , E_0 are, respectively, the electrostatic field in the presence of the sample, the electric displacement vector, the polarization vector, and the preexisting electrostatic field prior to sample insertion. The first integral must be taken over all space; the second extends over the volume of the sample, since P vanishes outside the confines of the specimen; (5) magnetic work (in Gaussian units): $\delta W = \int d^3r H \cdot dB/4\pi = \int_V d^3r H_0 \cdot dM$. Here, H , B , H_0 , and M are, respectively, the applied magnetic field in the presence of the sample, the magnetic induction, the applied magnetic field prior to insertion of the sample, and the magnetic moment vector. The above shows that work performance can always be determined from first principles; alternatively, it may be measured experimentally. This is of importance in what follows.

"The first law of thermodynamics" states in part that when work W_a is performed adiabatically (that is, on a system impervious to changes in temperature of the surroundings) thereby changing its state from x_1 to x_2 , then this change is independent of the type of work performed and independent of the path taken to effect this change. In these circumstances, one deals with a function of state, termed energy, here designated as U , that characterizes the x_1 to x_2 transformation via $\Delta U \equiv U_2 - U_1 = W|_a$. If now, the same process is carried out under nonadiabatic conditions, the $\Delta U = W$ equivalence no longer holds, thus seemingly impairing the usefulness of the energy concept. However, in the nonadiabatic process, additional changes take place that need to be considered.

The first law of thermodynamics asserts that there exists a function of state U , termed the internal energy, such that, for any process whatsoever that takes a system from an initial state x_n to a final state x_f , the difference $\Delta U \equiv U_f - U_n$ depends solely on the thermodynamic coordinates x_n and x_f and is independent of the path connecting these states. ΔU can be determined experimentally, or theoretically from $W|_a$. In nonadiabatic changes between the same states, ΔU remains exactly the same, but now the work performance W is different: $\Delta U - W \neq 0$. It is then expedient to introduce a deficit function Q , termed heat transfer, that reinstates the equality in the form: $Q - (\Delta U - W) = 0$. One thus arrives at the following formulation for the first law of thermodynamics:

$$\Delta U = Q + W \quad \text{or} \quad dU = \delta Q + \delta W \quad (3)$$

where the second formulation applies to an infinitesimal stage of the process; d and δ are used when one deals with infinitesimal processes that are not or are path dependent. Thus, Q and W are two different manifestations of energy in transit across the boundary separating the system from its surroundings. $Q > 0$ (< 0) increases (decreases) the energy of the system via an inflow (outflow) of heat; similarly, for the work transfer $W > 0$ (< 0). While Q , W , δQ , δW generally are path dependent, their sum in Eq. (3) is not. Thus, given a set of n thermodynamic variables $x = \{x_1, x_2, \dots, x_n\}$, the function of state U has the differential form of an analytic function:

$$dU = \sum_{j=1}^n (\partial U / \partial x_j) dx_j \quad (4)$$

Clearly, if processes occur totally within the system, there is no transfer of heat or work across the boundaries; then $\Delta U = 0$, which is an expression of the law of conservation of energy in an isolated system. This also disposes off the possibility of having a perpetual motion taking place.

Heat transfer, entropy, and the Second Law of Thermodynamics

The next law has been phrased in several different ways: the most common versions involve the statements enunciated by Kelvin and by Planck; these are derived below from more general principles. They are generally presented in elementary textbook

discussions that build up to the second law. There is nothing wrong logically with this procedure. However, intellectually it is rather unsatisfactory to base a fundamental thermodynamic principle on statements concerning the operation of a heat engine.

A more general formulation was provided by Carathéodory: in every neighborhood of any state of an adiabatically isolated system, there exist other states that cannot be accessed from it by any process. This statement really provides the proper theoretical background to the second law, but considerable mathematical sophistication is needed to show how this statement leads to the concept of entropy. Here, one can simplify matters by noting that just as one connected an adiabatic performance of work to the establishment of a function of state, a transfer of heat can also be used to the same end. Effectively, the first part of the second law of thermodynamics is equivalent to the statement that a reversible infinitesimal transfer of heat to a system $dQ|_r$, though path dependent, is related by a scaling (or integrating) factor λ to a new differential function of state, the empirical entropy s , via $ds = dQ|_r/\lambda$.

The determination of λ is accomplished through a set of tight arguments by considering the process of combining two systems A and B into a compound unit C. Let the heats transferred to the surroundings in an infinitesimal process be designated by dQ_a and dQ_b for the component parts, and by dQ_c for the compound system, $dQ_a + dQ_b = dQ_c$. Then, according to the second law,

$$ds_c = (\lambda_a/\lambda_c)ds_a + (\lambda_b/\lambda_c)ds_b \quad (5)$$

Let the deformation coordinates of A and B be given by $x_1, x_2, \dots, x_{n-1}, t$ and $y_1, y_2, \dots, y_{m-1}, t$ respectively, where t is the common empirical temperature of the compound system. Mathematically, one can then solve for x_{n-1} in terms of $x_1, x_2, \dots, x_{n-2}, t, s_a$ and for y_{m-1} in terms of $y_1, y_2, \dots, y_{m-2}, t, s_b$. It is now asserted that: (1) s_c must be independent of $x_1, x_2, \dots, x_{n-2}; y_1, y_2, \dots, y_{m-2}$ and t . If this were not so, Eq. (5) would necessarily contain terms involving the differential quantities $dx_1, dx_2, \dots, dy_{m-2}, dt$ (see Eq. 4). (2) The ratios λ_a/λ_c and λ_b/λ_c cannot depend on these variables; otherwise, statement (1) would be contradicted. (3) λ_c cannot depend on $y_1, y_2, \dots, y_{m-2}$; for, if it did, then λ_a in Eq. (5) would have to depend on these same coordinates in such a manner as to cancel out from the ratio λ_a/λ_c for consistency with statement (2) and (1). However, λ_a cannot possibly depend on the y -coordinates appropriate to system B. By the same reasoning, λ_c must be independent of $x_1, x_2, \dots, x_{n-2}$. (4) Furthermore, λ_a and λ_b cannot depend on $x_1, x_2, \dots, x_{n-2}$ and $y_1, y_2, \dots, y_{m-2}$, respectively. For, according to (3) these variables are missing from λ_c whence the ratios λ_a/λ_c and λ_b/λ_c must also be free of these variables, to remain consistent with (1), (2), and (3). However, this argument does not apply to t , which is common to A, B, and C. (5) As a consequence of (1)–(4), the functions λ_a, λ_b , and λ_c can involve at the most, the variables (s_a, t) , (s_b, t) , and (s_a, s_b, t) , respectively. (6) The functional dependences mentioned in (5) must have the form $\lambda_a = \varphi_a(s_a)T(t)$, $\lambda_b = \varphi_b(s_b)T(t)$, and $\lambda_c = \varphi_c(s_a, s_b)T(t)$, in which $T(t)$ is a common though arbitrary function of the empirical temperature t ; this function cancels from the ratios λ_a/λ_c and λ_b/λ_c in Eq. (5), in consonance with requirement (2). In summary, it is found that

$$\begin{aligned} dQ_a &= T(t)\varphi_a(s_a)ds_a \equiv T(t)dS_a \\ dQ_b &= T(t)\varphi_b(s_b)ds_b \equiv T(t)dS_b \\ dQ_c &= T(t)\varphi_c(s_a, s_b)ds_c \equiv T(t)dS_c \end{aligned} \quad (6)$$

where S in $dS_a \equiv \varphi_a(s_a)ds_a$, etc., is termed the metrical entropy. As described earlier, one can select any arbitrary function for T ; T is thus taken to be identical with the thermodynamic temperature scale of Eq. (2). Further, equilibrium conditions have been assumed throughout, so that all processes must be executed reversibly. Thus, one is led to the result

$$dQ|_r = T dS \quad (7)$$

which relates the state function S to the reversible transfer of heat across the boundaries of the system.

Now, the corollary of the second law is introduced as follows: For any process in a system in (adiabatic), isolation, the entropy of the final state is never less than that of the initial state. Thus, $dS|_a \geq 0$; the equality holds at equilibrium, and the inequality applies to processes taking place totally within an isolated system; thus, the entropy increases in such processes and reaches a maximum when equilibrium is attained.

Cyclic processes: The Clausius inequality

The relation between entropy and heat transfer is clarified by considering a process in which a system is taken reversibly from an initial state n to a final state f , involving a heat exchange $dQ|_r^{n-f}$. This is to be compared to the heat exchange $dQ|_i^{n-f}$ accompanying an irreversible process connecting the same states. From the first law, it is found that $dQ|_i^{n-f} - dQ|_r^{n-f} = -dW|_i^{n-f} + dW|_r^{n-f}$; dU , being a function of state, has been cancelled out. The above difference cannot vanish, since the two paths must necessarily differ. Thus, the algebraic sum must be either positive or negative. (1) Suppose $dQ|_i^{n-f} - dQ|_r^{n-f} \equiv -dQ|_i^{n-f} + dQ|_r^{f-n} < 0$, so that $-dW|_i^{n-f} + dW|_r^{f-n} = -dW|_i^{n-f} - dW|_r^{f-n} < 0$; that is, in going around one cycle (n - f - n), work has been performed on the system and an equivalent amount of heat has been transferred by the system to the surroundings. No other changes have taken place. (2) On the other hand, if the algebraic sum $dQ|_i^{n-f} + dQ|_r^{f-n}$ is assumed to be positive, a similar reasoning shows that during the cycle, heat has been introduced into the system, and an equivalent amount of work is obtained. To choose between the alternatives, consider the n - f process for which $dQ|_i^{n-f} \equiv dQ|_r^{n-f}$, $dQ|_r^{n-f} = T dS$. Then, under alternative (1) $T dS > dQ|_i$ in all circumstances, including the case where the n - f process is performed adiabatically, in which case $T dS|_a > 0$. No contradictions have been encountered. By contrast, in alternative (2) $T dS|_a < 0$, a conclusion that is unacceptable. One obtains the important result:

$dQ|_i < T dS = dQ_r$. Thus, in a reversible n-f process, the entropy change is matched by a heat transfer $dQ|_r/T$. If the same change is achieved irreversibly, the entropy change is the same but the heat transferred is smaller, the difference between $dQ|_r$ and $dQ|_i$ being made up by effects beyond experimental control. Also, for any process $dW|_i < dW|_r$ the maximum amount of work attainable involves a reversible process. Lastly, for finite changes, $S_f - S_n \geq \int_n^f dQ/T$; then, for a cyclic process where $S_f = S_n$, $\oint dS = \oint dQ/T \leq 0$. This latter result, which is consistent with $dQ|_i < dQ|_r$, is known as the Clausius inequality. The above brings up the problem of defining the temperature during irreversible processes; this is generally handled in two ways. One is to assume that the system is anchored to a huge reservoir whose temperature remains essentially fixed, while assuming that the heat transfer is sufficiently rapid to have that temperature also prevail in the system. The second is to note that in irreversible processes, for which departures from equilibrium are "small" (the linear regime of irreversibility), the temperature remains locally defined but varies with position. For more drastic departures from equilibrium, the temperature concept becomes more problematic.

Efficiencies of cyclic engines: Kelvin and Planck statements

One can now deal with the efficiency of any engine that operates in cycles while attached to a hot and a cold reservoir maintained at temperatures T_h and T_c respectively. All changes in the universe then occur solely in the surroundings. Let the heat transferred per cycle at the cold and hot junctions be $Q_c > 0$ and $Q_h > 0$, respectively; for the engine to operate, one requires $Q_h - Q_c > 0$, so that less heat is rejected at the cold end than was transferred into the engine at the hot end. Correspondingly, $W = -(Q_h - Q_c) < 0$ represents the amount of work transferable to the surroundings. The efficiency η is defined by the ratio of work output/heat input. The Clausius inequality as applied to the present process reduces to the sum $\sum_i Q_i/T_i = Q_h/T_h - Q_c/T_c \leq 0$; this may be converted to the inequality

$$-Q_c/Q_h \leq -T_c/T_h$$

Then,

$$\begin{aligned} \eta &= -W/Q_h = 1 - Q_c/Q_h \leq 1 - T_c/T_h \\ &= (T_h - T_c)/T_h \equiv \eta_{\text{Carnot}} \end{aligned} \quad (8)$$

The following are to be noted: (1) The generality of the approach; no mention is made of what types of cyclic engines are inserted between the two reservoirs. (2) The efficiency relates to the isothermal transfer of heat across the hot and cold junctions. (3) The efficiency for irreversible processes is less than that for reversible ones. (4) The efficiency is never unity since one cannot operate at the unattainable limits (see below) of $T = 0$ or $T \rightarrow \infty$. Thus, the efficiency never exceeds the Carnot efficiency η_{Carnot} . (5) η depends solely on the temperature of the "boiler" and "condenser" and, the bigger the temperature difference between them, the larger the efficiency is.

Statement (4) leads to Kelvin's statement of the second law: it is impossible to devise an engine operating in cycles that produces no effect other than to extract heat from a reservoir and to perform an equal amount of work. Also, one may infer the Clausius statement of the second law: it is impossible to devise a machine operating in cycles that transfers heat from a colder to a hotter body without producing other changes in the universe. If this were false, one could transfer heat without loss from the cold to the hot reservoir, so that $-Q_h/T_h + Q_c/T_c \leq 0$ with $Q_c = Q_h$, which would lead to the contradiction that $T_h/T_c \leq 1$.

Deficit functions and their use in setting up functions of state

The following discussion is much simplified by converting the Clausius inequality to an equality through the use of a deficit function $\delta\epsilon > 0$, such that $dQ|_r - \delta\epsilon = dQ|_i$; similarly, $dW|_r + \delta\epsilon = dW|_i$. In a closed universe consisting of system (energy U) and surroundings, (energy U_0) the first law leads to the expression $dU + dU_0 = 0 = dQ|_i + dW|_i + dU_0$, so that

$$T dS - \delta\epsilon + dW|_i - dU = T dS + dW|_r - dU = 0 \quad (9)$$

One imposes small deviations from the equilibrium, under a variety of constraints, and subsequently allows the system to relax to its original state. Such small deviations are symbolized by δ . Several cases are considered here:

- (1) The system is totally isolated; then $\delta Q = \delta W = \delta U = 0$, and Eq. (9) reduces to $T\delta S = \delta\epsilon \equiv T\delta\theta \geq 0$. Here, $\delta\theta = \delta\epsilon/T$ has been introduced as the entropy associated with the execution of irreversible processes that are not subject to external control. It is seen immediately that in an irreversible process taking place in an isolated system, the entropy can only increase, a point made earlier. When processes cease and equilibrium prevails, the entropy has achieved a maximum value.
- (2) If one allows isoenergetic processes to occur, where $\delta U = 0$ but $\delta Q = \delta W \neq 0$, then Eq. (9) reads as $T\delta S = \delta\epsilon + \delta Q|_i = \delta Q|_r$, which merely reinforces the fact that changes in entropy are tracked by reversible heat transfers. Also, if irreversible processes occur, the heat transfer is smaller; the entropy generated by processes outside experimental control is transferred as energy $\delta\epsilon$.
- (3) In isothermal processes for which $\delta T = 0$, Eq. (9) specializes to the form

$$\delta(U - TS) \equiv \delta A = \delta W|_i - \delta \varepsilon = \delta W|_r \quad (10)$$

where a new function of state, the Helmholtz free energy $A \equiv U - TS$ has been generated. This is tracked either by the performance of reversible work or by work over which the experimenter has control plus a component not under his control. If no work is performed, $\delta A = -\delta \varepsilon \leq 0$: any spontaneous process under the specified conditions reduces the Helmholtz free energy. When the processes have run their course and equilibrium prevails, A is at a minimum.

- (4) One next considers the isothermal-isobaric conditions for which $\delta T = \delta P = 0$. It is now expedient to write $\delta \varepsilon = \delta \varepsilon_m + \delta \varepsilon_t$, where the two terms refer to mechanical (P - V) and nonmechanical types of work; it may be shown that $\delta \varepsilon_m \geq 0$ and $\delta \varepsilon_t \geq 0$ separately. Eq. (9) now becomes

$$\delta(U - TS + PV) \equiv \delta G = \delta W_t|_i - \delta \varepsilon_t = \delta W_t|_r \quad (11)$$

wherein one introduces a new function of state, the Gibbs free energy $G \equiv U - TS + PV$. This quantity is tracked by reversible work other than mechanical ones; in irreversible processes, the work is augmented by energy transfers not subject to control. In the absence of work, $\delta G = -\delta \varepsilon_t \leq 0$, showing that under the stated conditions, the Gibbs free energy diminishes in spontaneous processes until it achieves a minimum at equilibrium.

- (5) Isentropic phenomena: here, S is fixed, so that from Eq. (9)

$$\delta U = -T \delta \theta + \delta W|_i = \delta W|_r \quad (12)$$

which merely repeats the first law, as specialized to adiabatic conditions. In the absence of work, $\delta U = -T \delta \theta \leq 0$, so that under the stated conditions, the energy is reduced and tends to a minimum at equilibrium.

- (6) For isentropic-isobaric conditions (P and S fixed), Eq. (9) specializes to

$$\delta(U + PV) \equiv \delta H = \delta W_t|_i - \delta \varepsilon = \delta W_t|_r \quad (13)$$

where yet another function of state, the enthalpy $H \equiv U + PV$, tracked by nonmechanical work, generally augmented by irreversibility effects, has been constructed. When no work is performed under the stated conditions, $\delta H = -T \delta \theta \leq 0$, so that once more H diminishes in irreversible phenomena and achieves a minimum at equilibrium.

Among the most frequently used functions of state is the chemical potential, derived from Eq. (11) as $\mu = (\partial G / \partial n_i)_{T, P, n_{j \neq i}}$, where n_i represents the mole number of species i in the system. The utility of this function arises in part because it involves T and P as independent variables; these are precisely the quantities that are readily subject to experimental control. The second useful feature hinges on the fact that at equilibrium, μ is a minimum. Different phases are associated with different chemical potentials that vary differently with T and P . The phase among competing phases that prevails under a given set of conditions is the one with the lowest μ . As conditions change, the relative values of μ for the different possible phases are also altered, and a transition from one phase to another takes place whenever the chemical potential of a particular phase falls below that of a previously stable phase. Two phases coexist under conditions where their chemical potentials are the same. This very general subject area has vast ramifications that cannot be explored here.

Standard formulation for differentials of state functions: Maxwell relations

The above functions of state are summarized in Table 1. They lead to the various standard differential forms displayed in part A; note that all work other than mechanical has been excluded. If other types of work are to be included, one must adjoin to these equations, the appropriate work differentials (refer to those listed above).

Table 1 Standard formulations for thermodynamic functions of state and resulting relations.

A. Legendre transformations

From the definitions for $H = U + PV$, $A = U - TS$, $G = U - TS + PV$, and the fundamental relation for dU , one obtains

$$dU = T dS - P dV \quad dA = -S dT - P dV \quad (1.1, 1.3)$$

$$dH = T dS + V dP \quad dG = -S dT + V dP \quad (1.2, 1.4)$$

If work other than mechanical is involved, those terms must also be included.

B. First derivatives

$$T = (\partial U / \partial S)_V = (\partial H / \partial S)_P \quad V = (\partial H / \partial P)_S = (\partial G / \partial P)_T \quad (1.5, 1.6)$$

$$S = -(\partial A / \partial T)_V = -(\partial G / \partial T)_P \quad P = -(\partial U / \partial V)_S = -(\partial A / \partial V)_T \quad (1.7, 1.8)$$

C. Cross-derivatives, Maxwell relations

$$(\partial T / \partial V)_S = -(\partial P / \partial S)_V \quad (\partial S / \partial P)_T = -(\partial V / \partial T)_P \quad (1.9, 1.10)$$

$$(\partial T / \partial P)_S = (\partial V / \partial S)_P \quad (\partial S / \partial V)_T = (\partial P / \partial T)_V \quad (1.11, 1.12)$$

The process of generating the differentials dH , dA , and dG from dU is called a Legendre transformation. These differential functions of state are very useful in determining the thermodynamic properties of systems. Taking first derivatives leads to the results shown in part B; by taking cross derivatives in either order, one obtains the so-called Maxwell relations shown in part C. Once the equation of state $P = P(T, V)$ or $V = V(T, P)$ is known, one can integrate (I.10) and (I.12) to find S as a function of T and V or T and P . Alternatively, one may employ Eq. (I.7) if A or G are known, for example, from statistical mechanics.

Other deductions are found by substituting $S = S(T, V)$ or $S = S(T, P)$ into $U(S, V)$ or $H = H(S, P)$ to obtain $U = U(S(T, V), V) = U(T, V)$, and

$$H = H(S(T, P), P) = H(T, P), \text{ so that}$$

$$dU = T(\partial S/\partial T)_V dT + [T(\partial S/\partial V)_T - P]dV$$

$$= (\partial U/\partial T)_V dT + (\partial U/\partial V)_T dV \quad (14a)$$

$$dH = T(\partial S/\partial T)_P dT + [T(\partial S/\partial P)_T + V]dP$$

$$= (\partial H/\partial T)_P dT + (\partial H/\partial P)_T dP \quad (14b)$$

Comparing the coefficients leads to the results

$$(\partial U/\partial T)_V = T(\partial S/\partial T)_V \equiv C_V$$

$$(\partial H/\partial T)_P = T(\partial S/\partial T)_P \equiv C_P \quad (15a)$$

$$(\partial U/\partial V)_T = T(\partial S/\partial V)_T - P$$

$$= T(\partial P/\partial T)_V - P(V, T) \quad (15b)$$

$$(\partial H/\partial P)_T = T(\partial S/\partial P)_T + V$$

$$= -T(\partial V/\partial T)_P + V(P, T) \quad (15c)$$

The appropriate Maxwell relations have been introduced on the right-hand side of Eqs. (15b), (15c). The symbols C_P and C_V represent the heat capacities at constant pressure and volume; these are readily measurable as a function of temperature. This permits the determination of U and H as a function of T , with either V or P as a parameter. Eqs. (15b), (15c) are known as caloric equations of state; insertion of the equations of state $P(T, V)$ or $V(T, P)$ into these relations, followed by integration, enables one to determine $U = U(T, V)$ and $H = H(T, P)$. Also, from (15a), after measurements of C_V or C_P as a function of T , followed by integration, one can determine $S = S(T, V)$ or $S = S(T, P)$. In a series of lengthy but elementary steps listed in all textbooks, one finds that $C_P - C_V = \alpha^2 VT/\beta$, with $\alpha \equiv V^{-1}(\partial V/\partial T)_P$ representing the isobaric expansion coefficient, and $\beta \equiv -V^{-1}(\partial V/\partial P)_T$, the isothermal compressibility of the material. This difference relation is of importance because it is easier to measure C_P experimentally, whereas the quantity useful in theoretical analysis is C_V . Lastly, insertion of Eq. (I.7) into $A = U - TS$ leads to $A = U + T(\partial A/\partial T)_V$; similarly, $G = H + T(\partial G/\partial T)_P$. These are known as "Gibbs-Helmholtz equations," which may be converted into the partial differential forms involving $(\partial A/\partial T)_V = A/T - U/T$ and $(\partial G/\partial T)_P = G/T - H/T$, whose solution, after insertion for U or H yields A or G .

Eq. (I.7) is particularly useful in determining the entropy when the dependence of A or G on T is known from other sources. Eqs. (I.10), (I.12) permit substitution for entropy derivatives in terms of information derived from the equations of state.

The Third Law of Thermodynamics: Unattainability of zero temperature

The "third law of thermodynamics" deals with events as $T \rightarrow 0$, where dQ/T might diverge. One first demonstrates that zero temperature is unattainable. Consider the general case where z represents a deformation coordinate and Z is the conjugate variable, such that the first law assumes the form $dS = T^{-1}[dU + Z dz] = T^{-1}\{(\partial U/\partial T)dT + [Z + (\partial U/\partial z)]dz\}$. Below, one needs the result of the cross differentiation of this expression with respect to T and z , namely $Z + (\partial U/\partial z) = T(\partial Z/\partial T)$. Special interest now attaches to the case $dS = 0$, since only under adiabatic conditions, one can hope to reach the lowest possible temperature. Imposing this requirement leads to

$$dT = \{[Z + (\partial U/\partial z)]/(\partial U/\partial T)\}dz \quad (16)$$

This relation shows that any change in deformation coordinates under isentropic (adiabatic) conditions necessarily changes the temperature of the system. Insertion of the cross differentiation result leads to the requirement

$$dT = -T[(\partial Z/\partial T)_z/(\partial U/\partial T)_z]dz$$

$$= -[T(\partial Z/\partial T)_z/C_z]dz \quad (17)$$

$$= -(T/C_z)(\partial S/\partial z)_T dz,$$

where Eq. (I.12) with the correspondences P, Z , and $V; z$ was introduced on the right-hand side. Whether $T = 0$ can be achieved or not, thus, hinges on the properties of $(\partial Z/\partial T)_z$ and of (T/C_z) at exceedingly low temperatures. In the experience of mankind, both

quantities approach zero as $T \rightarrow 0$, but $(\partial Z/\partial T)_z$ does so more rapidly than does C_z/T . Thus, the limit $T = 0$ is unattainable. Moreover, $(\partial S/\partial z)_T \rightarrow 0$ in this limit, which is an important statement that becomes part of the third law.

Based on these findings, one can now state the third law of thermodynamics which asserts that as $T \rightarrow 0$, the entropy of any system tends toward a least value when the system is in its lowest energy state and, as the thermodynamic coordinates are altered, approaches this value with zero slope. The wording implies that the system must actually have reached its equilibrium state, hence, its lowest energy, on cooling to the lowest possible temperature. Contrary to statements in some textbooks, it is not claimed that $S \rightarrow 0$ as $T \rightarrow 0$. Liquid mercury under ambient pressure, disordered solid solutions or amalgams, random elemental isotopic abundances, are common counter examples. However, if in any given process these types of ground states are left undisturbed, it is effectively permissible to set $S = 0$ at $T = 0$, much as the gravitational energy of a quiescent system at sea level is assigned an energy zero.

Thermodynamics of anisotropic media

Lastly, the deformation of anisotropic solids is considered. Let $\mathbf{s}(\mathbf{r})$ and $\mathbf{s}(\mathbf{r} + d\mathbf{r})$ be the displacement vectors that move element A , originally at $\mathbf{r}$, to $\mathbf{r} + \mathbf{s}(\mathbf{r})$, and neighboring element B , originally at $\mathbf{r} + d\mathbf{r}$ to new locations. For small displacements, $\mathbf{s}(\mathbf{r} + d\mathbf{r}) \approx \mathbf{s}(\mathbf{r}) + d\mathbf{r} \cdot \nabla \mathbf{s}(\mathbf{r})$. Here, $\nabla \mathbf{s}(\mathbf{r})$ is a matrix (a tensor) with columns $\partial s_x(\mathbf{r})/\partial x$, $\partial s_x(\mathbf{r})/\partial y$, and $\partial s_x(\mathbf{r})/\partial z$, and similarly with $s_y(\mathbf{r})$ and $s_z(\mathbf{r})$. Now, any matrix with entries M_{ij} may be rewritten as $M_{ij} = (1/2)(M_{ij} + M_{ji}) + (1/2)(M_{ij} - M_{ji})$, involving a symmetric ($\mathbf{e}_s$) and an antisymmetric component, $\mathbf{e}_a$. The matrix for $\nabla \mathbf{s}(\mathbf{r}) = \mathbf{e}_s + \mathbf{e}_a$ is shown for $\mathbf{e}_s$ in Table 2, with entries $e_{ij} = (1/2)[\partial s_i/\partial r_j + \partial s_j/\partial r_i]$. For the $\mathbf{e}_a$ entries, the "+" sign is replaced by "-", so that the diagonal elements of $\mathbf{e}_a$ vanish.

Consider now a dilatation of a solid in which element A at $\mathbf{r}$ is displaced by $\mathbf{s}(\mathbf{r})$ to A' , and a neighboring element B at $\mathbf{r} + d\mathbf{r}$ is displaced to B' by $\mathbf{s}(\mathbf{r} + d\mathbf{r})$. The $A'B'$ separation distance is then $d\mathbf{r}' = d\mathbf{r} + [\mathbf{s}(\mathbf{r} + d\mathbf{r}) - \mathbf{s}(\mathbf{r})] \approx d\mathbf{r} + d\mathbf{r} \cdot \nabla \mathbf{s}(\mathbf{r}) = d\mathbf{r} + d\mathbf{r} \cdot (\mathbf{e}_s + \mathbf{e}_a)$. Note that $\mathbf{e}_a$ represents a pure rotation; on rotating the coordinate system by $-\mathbf{e}_a$, one obtains $d\mathbf{r}' = d\mathbf{r} + d\mathbf{r} \cdot \mathbf{e}_s$ in the rotated system. Here, $d\mathbf{r}$ is the row vector $[dx, dy, dz]$ and the $\mathbf{e}_s$ matrix is shown in Table 2.

A linear dilatation along x is then specified by $d\mathbf{x}' = (1 + e_{xx})d\mathbf{x} + e_{yx}d\mathbf{y} + e_{zx}d\mathbf{z}$, with similar expressions for $d\mathbf{y}'$ and $d\mathbf{z}'$. Thus, the diagonal element e_{xx} of Table 2 indicates the fractional lengthening of the solid along the x -axis, and similarly, for y and z . Angular dilatations, on the other hand, involve a displacement $d\mathbf{l}$ whereby $\hat{\mathbf{i}} \cdot d\mathbf{l}$ originally perpendicular to $\hat{\mathbf{j}} \cdot d\mathbf{l}$ ($\hat{\mathbf{i}}$ and $\hat{\mathbf{j}}$ are orthogonal unit vectors along x and y) now change into $A_x \equiv \hat{\mathbf{i}} \cdot d\mathbf{l} + \hat{\mathbf{i}} \cdot d\mathbf{l} \cdot \mathbf{e}_s = \hat{\mathbf{i}}(1 + e_{xx})d\mathbf{l} + \hat{\mathbf{j}}e_{xy}d\mathbf{l} + \hat{\mathbf{k}}e_{xz}d\mathbf{l}$, and $A_y \equiv \hat{\mathbf{j}} \cdot d\mathbf{l} + \hat{\mathbf{j}} \cdot d\mathbf{l} \cdot \mathbf{e}_s = \hat{\mathbf{i}}e_{yx}d\mathbf{l} + \hat{\mathbf{j}}(1 + e_{yy})d\mathbf{l} + \hat{\mathbf{k}}e_{yz}d\mathbf{l}$. The angle between

A_x and A_y in the x - y -plane is specified by

$$\cos \phi_{xy} = \frac{(\hat{\mathbf{i}} \cdot d\mathbf{l} + \hat{\mathbf{i}} \cdot d\mathbf{l} \cdot \mathbf{e}_s) \cdot (\hat{\mathbf{j}} \cdot d\mathbf{l} + \hat{\mathbf{j}} \cdot d\mathbf{l} \cdot \mathbf{e}_s)}{|\hat{\mathbf{i}} \cdot d\mathbf{l} + \hat{\mathbf{i}} \cdot d\mathbf{l} \cdot \mathbf{e}_s| \times |\hat{\mathbf{j}} \cdot d\mathbf{l} + \hat{\mathbf{j}} \cdot d\mathbf{l} \cdot \mathbf{e}_s|} \quad (18)$$

When the appropriate entries for $\mathbf{e}_s$ are introduced and an expansion is carried out to first order in e_{ij} , one obtains (after a large number of elementary steps) $\cos \phi_{xy} \approx 2e_{xy}$. Now, introduce the deviation from the right angle by $\Omega_{xy} = \pi/2 - \phi_{xy}$, so that $\cos \phi_{xy} \approx \Omega_{xy} \approx 2e_{xy}$. Similarly, $\Omega_{xz} \approx 2e_{xz}$, $\Omega_{yz} \approx 2e_{yz}$.

It is conventional to introduce a more compact notation for the strain components, as shown in part B of Table 2; also, one sets up six components of a stress tensor $\boldsymbol{\sigma}$ that induces the strain. Here, $\sigma_i = [\partial(U/V)/\partial e_i]_{e_j \neq i}$; these are listed in part C of Table 2. The element of work is then given by $V \sum_i \sigma_i de_i$.

Table 2 Matrix entries for deformation of anisotropic materials.

A. Entries to the symmetric strain tensor

$$\mathbf{e} = \begin{bmatrix} e_{xx} & e_{xy} & e_{xz} \\ e_{yx} & e_{yy} & e_{yz} \\ e_{zx} & e_{zy} & e_{zz} \end{bmatrix} \quad \begin{aligned} e_{xx} &= (\partial s_x / \partial x) & e_{xy} &= (1/2)[(\partial s_x / \partial y) + (\partial s_y / \partial x)] = e_{yx} \\ e_{yy} &= (\partial s_y / \partial y) & e_{xz} &= (1/2)[(\partial s_x / \partial z) + (\partial s_z / \partial x)] = e_{zx} \\ e_{zz} &= (\partial s_z / \partial z) & e_{yz} &= (1/2)[(\partial s_z / \partial y) + (\partial s_y / \partial z)] = e_{zy} \end{aligned}$$

B. Conventional notation for strain components

$$\begin{aligned} e_1 &\equiv e_{xx}, & e_2 &\equiv e_{yy}, & e_3 &\equiv e_{zz} \\ e_4 &\equiv 2e_{xy} = 2e_{yx}, & e_5 &\equiv 2e_{xz} = 2e_{zx}, & e_6 &\equiv 2e_{yz} = 2e_{zy} \end{aligned}$$

C. Conventional notation for stress components

$$\begin{aligned} \sigma_1 &\equiv \sigma_{xx} \text{ pressure along } x & \sigma_4 &\equiv \sigma_{xy} = \sigma_{yx} \text{ pressure } \perp x \text{ along } y \text{ or vice versa} \\ \sigma_2 &\equiv \sigma_{yy} \text{ pressure along } y & \sigma_5 &\equiv \sigma_{xz} = \sigma_{zx} \text{ pressure } \perp x \text{ along } z \text{ or vice versa} \\ \sigma_3 &\equiv \sigma_{zz} \text{ pressure along } z & \sigma_6 &\equiv \sigma_{yz} = \sigma_{zy} \text{ pressure } \perp y \text{ along } z \text{ or vice versa} \end{aligned}$$

Table 3 Maxwell relations for anisotropic solids; constant V .

$$\begin{aligned} \frac{1}{V} \left(\frac{\partial S}{\partial e_i} \right)_T &= - \left(\frac{\partial \sigma_i}{\partial T} \right)_{e_i} & \frac{1}{V} \left(\frac{\partial S}{\partial \sigma_i} \right)_T &= \left(\frac{\partial e_i}{\partial T} \right)_{\sigma_i} \quad (\text{III.1, III.2}) \\ \frac{1}{V} \left(\frac{\partial S}{\partial \sigma_i} \right)_{e_i} &= \left(\frac{\partial e_i}{\partial T} \right)_S & \frac{1}{V} \left(\frac{\partial S}{\partial e_i} \right)_{\sigma_i} &= - \left(\frac{\partial \sigma_i}{\partial T} \right)_S \quad (\text{III.3, III.4}) \end{aligned}$$

With these definitions, the above concepts are embedded in thermodynamics by writing the differential of the energy (of the strained relative to the unstrained body) as

$$dU = T dS + V \sum_{i=1}^6 \sigma_i de_i \quad (19)$$

One should note the positive sign ahead of the second term: work is done by the system as the strain is diminished. Next, the enthalpy, by $H = U - \sum_{i=1}^6 \sigma_i (Ve_i)$ is introduced. The enthalpy differential is then given by

$$\begin{aligned} dH &= dU - V \sum_{i=1}^6 e_i d\sigma_i - V \sum_{i=1}^6 \sigma_i de_i \\ &= T dS - V \sum_{i=1}^6 e_i d\sigma_i \end{aligned} \quad (20)$$

From (19) and (20), Maxwell relations may be constructed in the usual manner; these are listed in Table 3: integration then specifies the entropy of the solid in its dependence on σ_i or on e_i under different conditions (for details, see the “Further reading” section).

Moreover, from the definition of the stress tensor, it follows that

$$\left(\partial \sigma_i / \partial e_j \right)_{S, e_{j \neq i}} \equiv c_{ij} \Big|_S = \left(\partial \sigma_j / \partial e_i \right)_{S, e_{j \neq i}} \equiv c_{ji} \Big|_S \quad (21a)$$

$$\left(\partial \sigma_i / \partial e_j \right)_{T, e_{j \neq i}} \equiv c_{ij} \Big|_T = \left(\partial \sigma_j / \partial e_i \right)_{T, e_{j \neq i}} \equiv c_{ji} \Big|_T \quad (21b)$$

which are known as isentropic and isothermal elastic stiffness coefficients. The inverse $(\partial \sigma_i / \partial e_j)_{S, \sigma_{j \neq i}}$ or $(\partial \sigma_i / \partial e_j)_{T, \sigma_{j \neq i}}$ represent isentropic and isothermal compliance coefficients. There also exist six thermal strain coefficients $\alpha_i \equiv (\partial e_i / \partial T)_{\sigma_j}$ and six thermal stress coefficients $\delta_i \equiv (\partial \sigma_i / \partial T)_{e_j}$ that deal with the temperature variations of the respective coefficients.

This completes the brief survey of commonly used coefficients that characterize the deformation of anisotropic elastic solids.

Application of thermodynamic concepts

The basic concepts developed above find many applications in condensed matter physics. Several important uses are briefly listed. Prominent among these is the determination of heat capacities of materials as a function of temperature, from which the energy, enthalpy, and entropy may be found by integration of Eq. (15a).

An entire subdiscipline deals with phase equilibria, phase diagrams, phase transitions, and related aspects. All these topics are ultimately based on the properties of the chemical potential, briefly alluded to in an earlier section of the present article. Phase diagrams obtained from empirical measurements are of cardinal importance in the entire manufacturing process and industrial output of chemicals in developed countries.

Another subdiscipline deals with the properties of matter, energy, and entropy flow, as determined by irreversible thermodynamics.

Thermal properties of materials represent another area of great contemporary interest. Here, the properties of anisotropic media discussed above, represent the proper theoretical background for a rationalization of experimental results.

Results based on the third law of thermodynamics provide the basic theoretical framework for interpreting a large number of studies dealing with properties of materials at ultralow temperatures. The operation of cyclic engines, described briefly above, is another area where thermodynamics plays an important role. Lastly, by considering the various different types of work alluded to in the introduction to the first law, one can extend the above thermodynamic principles to new areas, such as electromagnetic properties, surface adsorption phenomena, curved surfaces, radiation, processes in gravitational fields, and the like. Their detailed discussion must be left to specialized monographs. They form the foundation for explaining many physical characteristics of condensed matter, such as magnetic and electrical properties, the interaction of condensed phases with electromagnetic radiation, and interfacial phenomena.

Reprise and extension of fundamentals

It is instructive to extend the earlier discussion of the laws of thermodynamics by including the significant role of the surroundings, and featuring the distinction between reversible and irreversible heat transfers and work performance. To this end we study the interaction of a system, uniformly characterized by independent variables T, V, n_j , with its surroundings, characterized by the variables $T_0, V_0, n_{0,j}$. The surroundings are assumed to be so vast as to remain essentially constant, or respond to the system in a reversible manner, even when the system itself undergoes irreversible processes. All irreversible processes are assumed to occur such that in an infinitesimal advance the thermodynamic variables of the system change nearly uniformly during their interaction with the external world. The system and surroundings of the compound unit are separated by a thin barrier, across which quantities such as the temperature change from T to T_0 . Processes within this small interface are ignored. Analogous remarks apply to all other intensive variables, such as pressure or chemical potential.

Even though the above restrictions are somewhat unrealistic the corresponding processes are instructive. Examine first a reversible process (r) that involves heat exchanges between system and surroundings, both at constant volume and composition. During an infinitesimal step the corresponding entropy change, $d_r S_u$ in the universe is the sum of the entropy change dS of the system, and the compensating entropy change $d_r S_0$ of the surroundings at the temperature T almost equal to T_0 . In the present case there is no net change in entropy in the compound system:

$$d_r S_u \equiv dS(T, V, n_j) + d_r S_0(T, V_0, n_{0,j}) = 0. \quad (22a)$$

Next, let the same change of the system take place irreversibly (i) while the reservoir, operating reversibly, remains at temperature T_0 . The irreversible operation occurs under conditions that can still be maintained at a more – or – less uniform average value T . Since entropy is a function of state of the system, $dS(T, V, n_j)$ is the same as before, but the entropy change in the surroundings, $d_i S_0(T_0, V_0, n_{0,j})$, is now different. According to the Second Law the entropy of the universe can only increase, so that

$$d_i S_u \equiv dS(T, V, n_j) + d_i S_0(T_0, V_0, n_{0,j}) > 0. \quad (22b)$$

The use of inequalities is always awkward; we avoid several problems by introducing an entropy deficit function $\delta\theta > 0$ that converts Eq. (22b) into an equality:

$$d_i S_u \equiv dS(T, V, n_j) + d_i S_0(T_0, V_0, n_{0,j}) - \delta\theta = 0. \quad (22c)$$

We encounter a notational problem here: $d_i S_0(T_0, V_0, n_{0,j})$ refers to a reversible process in the surroundings in response to an irreversible process in the system.

So far $\delta\theta$ is simply a bookkeeping device. However, it acquires meaning when we subtract Eq. (22a) from Eq. (22c) to write

$$d_i S_0(T_0, V_0, n_{0,j}) - d_r S_0(T, V_0, n_{0,j}) = \delta\theta \quad (22d)$$

whereby $\delta\theta$ represents the entropy difference in the surroundings when the infinitesimal step $dS(T, V, n_j)$ within the system is carried out irreversibly as opposed to reversibly.

The system + surroundings form a closed unit, so that the infinitesimal heat ($\delta_i Q$) lost (gained) irreversibly by the system operating at temperature T is gained (lost) by the surroundings ($\delta_r Q_0$) operating reversibly at temperature T_0 . Thus, necessarily, $-\delta_i Q = \delta_r Q_0$. It is only in the limit $T - T_0 \rightarrow 0$ that the heat transfer from or to the system can be carried out reversibly.

During the reversible step (r) at the common temperature T the infinitesimal entropy change of the system is given by $dS \equiv d_r S = \delta_r Q/T$; hence, by Eq. (22a), the entropy change in the surroundings is specified by

$$\delta_r S_0 = -dS = -\delta_r Q/T. \quad (23a)$$

For the same step executed irreversibly (i), with the temperature of the system at T and that of the surroundings at T_0 , the heat exchange $\delta_i Q = -\delta_r Q_0$ produces an entropy change in the surroundings as

$$d_i S_0 = \delta_r Q_0/T_0 = -\delta_i Q/T_0, \quad (23b)$$

where we invoked the reversibility of all processes in the reservoir.

On inserting Eqs. (23a) and (23b) into Eq. (22d) we obtain the fundamental relation

$$\delta_i Q = (T_0/T)\delta_r Q - T_0\delta\theta = T_0(dS - \delta\theta) < (T_0/T)\delta_r Q. \quad (24a)$$

The inequality is self-evident for the case where heat is transferred into the system; here $\delta_i Q$ and $\delta_r Q$ are both positive, with $T < T_0$. Moreover, this result must apply for any $T < T_0$, and particularly, to the limiting case $T = T_0$. One thereby obtains a tighter constraint, as a string of inequalities:

$$\delta_i Q < \delta_r Q < (T_0/T)\delta_r Q, \quad (24b)$$

where the first inequality is a version of the **Clausius Inequality**. Implicit in the above is the assumption that in the limiting case $d\theta$ does not necessarily vanish: as an example, consider the case where the reversible heating of the system triggers a spontaneous reaction totally within the sample.

When heat is transferred out of the system, with $T > T_0$, Eq. (24a) shows that $\delta_i Q$ is more negative than $(T_0/T)\delta_r Q$. This result applies as well to any $T > T_0$, and thus, to the limiting case $T = T_0$. We then recover a string of increasingly less negative quantities going from left to right in Eq. (24b).

Eq. (24a) may be restated in the equivalent form

$$\delta_i Q = \delta_r Q + (T_0/T - 1) \delta_r Q - T_0 d\theta, \quad (24c)$$

where the last two terms specify the difference between the heat transferred irreversibly in the infinitesimal step, $\delta_i Q$, and that transferred reversibly, $\delta_r Q$, in executing the same step.

When the temperature of the system and reservoir differ only infinitesimally, $T \approx T_0$, Eq. (24c) reduces to

$$\delta_i Q = \delta_r Q - T d\theta = T(dS - d\theta). \quad (24d)$$

Here $T d\theta$ may be interpreted as the difference in heat transfers executed reversibly and irreversibly under these limited conditions, as may happen if an otherwise reversible heat transfer into the system triggers additional irreversible phenomena totally within the system. Eq. (24d) shows directly that the irreversible heat transfer is less positive or more negative than its reversible counterpart.

One may also turn Eq. (24a) around to read

$$dS = \delta_i Q/T_0 + d\theta > \delta_i Q/T_0, \quad (24e)$$

which shows explicitly that in irreversible processes the total entropy change in the system is only partially accounted for by the exchange of heat. Note that it is the well established temperature of the reservoir that always enters the expression. The above should be contrasted with the usual relation $dS = \delta_r Q/T$, in which the entropy change is completely tracked by the reversible heat transfer at the common temperature T . Eq. (24e) represents the Clausius Inequality.

Eq. (24e) merits further careful scrutiny. In the above infinitesimal step that carries the system from state A to state B, dS is always the total concomitant entropy change. In the absence of any work or compositional changes the only channel for outside communication is the transfer of heat, as shown by the first term on the right. This then dictates that the $d\theta$ term represents the additional contribution to dS arising from purely reconfigurations of the system that are outside the control of the experimenter.

Performance of work

Next, we reintroduce the First Law of Thermodynamics. Because the energy E is a function of state we set

$$dE = \delta_r Q + \delta_r W = \delta_i Q + \delta_i W, \quad (25a)$$

where W is the work performed during the process. On eliminating $\delta_i Q$ between Eqs. (24c), and (25a) we may solve for

$$\delta_i W = \delta_r W - (T_0/T - 1) \delta_r Q + T_0 d\theta = \delta_r W - (T_0 - T) dS + \delta \epsilon, \quad (25b)$$

where $T_0 d\theta \equiv \delta \epsilon$ represents the infinitesimal difference in work performance under reversible as opposed to irreversible conditions. A special case of interest involves processes that are carried out under conditions where T and T_0 differ only infinitesimally, so that

$$\delta_i W = \delta_r W + T_0 d\theta \equiv \delta_r W + \delta \epsilon. \quad (25c)$$

We now note that the last two terms on the right in Eq. (25b) differ in sign from those in Eq. (24c) and therefore are positive. This leads to the inequality

$$\delta_i W > \delta_r W, \quad (25d)$$

which indicates, in accord with intuition, that work executed in carrying out a particular process irreversibly always exceeds work carried out reversibly, whether work is done on or by the system. In the latter case less useful work is obtained from the system operating irreversibly.

Another significant feature of the present analysis is found by solving Eq. (25b) for

$$d\theta = (\delta_i W - \delta_r W)/T_0 + (1 - T/T_0) dS. \quad (26)$$

This relation expresses the contribution of irreversible phenomena to the infinitesimal entropy change, in terms of quantities that may be measured or calculated. It requires monitoring the entropy change in the system while carrying out a given process reversibly. Also, one needs to determine the work for executing the same change reversibly and irreversibly. Work executed in any

given process may always be determined experimentally; the work involved in a reversible process may be calculated. Thus, the right hand side of Eq. (26) is experimentally accessible.

Conclusion

A brief review of the four basic laws of thermodynamics has been provided, based on standard operations covered in the literature. Much of the present discussion is based on the distinction between reversible and irreversible phenomena. This is followed by discussion with special emphasis on the interaction between the system and its surroundings, thus obviating the need of inequalities in discussing the exchange of heat and work. For more detailed information of all the topics raised above the reader is directed to the vast accumulation of articles and books that have accumulated of over 160 years, calling for a firm grasp of the fundamental principles.

Irreversible thermodynamics as applied to basic electron transport theory in solids[☆]

Abstract

An overview of basic ideas in irreversible thermodynamics as they apply to electron transport phenomena in solids is provided; the theory is thus not presented in its full generality. The discussion is limited to systems that are at rest, remain at constant volume, undergo no chemical changes, are isotropic, and for which steady-state conditions hold. In these circumstances, the ordinary time differential operator d/dt and its partial counterpart, $\partial/\partial t$, are equivalent, and the tensorial notation can be dispensed with. Readers who desire a full introduction to irreversible phenomena should consult the listings under “Further reading” section. The discussion is also limited to the linearized regime, in which departures from equilibrium are small, such that intensive variables such as temperature, pressure, concentration, chemical potential, and the like retain their significance locally. However, these variables are presumed to vary with position in such a manner that their gradients are small compared to their values averaged over the system.

Key points

- Heat transfer is governed by Fourier's Law, Eq. (5).
- The entropy change associated with heat transfer is specified by Eq. (8).
- The mass transfer, energy change, and entropy change during heat transfer is specified by Eqs. (10), (14), (16) respectively.
- Thermoelectric processes are described in terms of Seebeck coefficients, Eq. (25), Peltier effects, Eqs. (27a)–(27e), and Thomson coefficients.
- Magnetic field effects are displayed in Eqs. (28a)–(28d), subject to the Casimir-Onsager relations.
- Special are discussed in detail: Ohm's Law in magnetic fields, the Hall effect, the Ettingshausen effect, the adiabatic and isothermal Hall effects, thermal conductivity, thermoelectric phenomena via the Seebeck coefficient, the Nernst effect, the Righi-Leduc coefficients.
- Various transport coefficients of Eqs. (28a)–(28d) are re-expressed in terms of the coefficients specified above via Eq. (35).

[☆]Change History: September 2022. JM Honig updated the chapter.

- One-band transport coefficients are generated by Eqs. (36a)–(36d).
- Transport coefficients for p-n band solids are assembled in Table 1.
- Transport coefficients in the limit of small magnetic fields are assembled in Table 2.

Introductory comments

An overview of basic ideas in irreversible thermodynamics as they apply to electron transport phenomena in solids is provided; the theory is thus not presented in its full generality. The discussion is limited to systems that are at rest, remain at constant volume, undergo no chemical changes, are isotropic, and for which steady-state conditions hold. In these circumstances, the ordinary time differential operator d/dt and its partial counterpart, $\partial/\partial t$, are equivalent, and the tensorial notation can be dispensed with. Readers who desire a full introduction to irreversible phenomena should consult the listings under “Further reading” section. The discussion is also limited to the linearized regime, in which departures from equilibrium are small, such that intensive variables such as temperature, pressure, concentration, chemical potential, and the like retain their significance locally. However, these variables are presumed to vary with position in such a manner that their gradients are small compared to their values averaged over the system.

Elementary description of heat and mass transport

Transfer of heat between two different systems

To begin with, a heuristic introduction of basic concepts characterizing relaxation processes that lead toward establishment of equilibrium conditions is given. Consider two isolated regions in space, designated by (and at) temperatures T' and T'' ; when brought into contact (see Fig. 1), and on allowing the intervening partition to become slightly diathermic, heat is slowly transferred between the compartments. If the enlarged unit remains isolated, and the interfacial phenomena are ignored, the energies, E' and E'' , of the two subsystems are additive, as are the entropies $S'(E', V')$ and $S''(E'', V'')$. Assume further that the volumes V' and V'' remain fixed. Then the first and second laws of thermodynamics lead to the relations

$$dE' + dE'' = 0 \quad (1a)$$

$$dS = (\partial S'/\partial E')_{V'} dE' + (\partial S''/\partial E'')_{V''} dE'' \geq 0 \quad (1b)$$

On account of Eq. (1a) and with $(\partial E/\partial S)_V = T$, where T is the temperature of the bulk of the system, Eq. (1b) becomes

$$dS = (1/T'' - 1/T') dE'' \geq 0 \quad (2)$$

which immediately establishes the requirement $T' = T''$ as a necessary condition for thermal equilibrium. Moreover, according to the second law, as equilibrium is established, the total entropy of the isolated compound system increases toward a maximum, consistent with the remaining constraints. Hence, the time derivative of the total entropy, $\dot{S} \equiv (dS/dt)$, may be written as

$$\dot{S} = (1/T'' - 1/T') (dE''/dt) \geq 0 \quad (3)$$

In the present case, no work has been performed and no material has been transferred; therefore, all energy changes involve solely a transfer of heat between the two subsystems. It is then appropriate to identify dE''/dt with the rate of heat transfer Q across the boundary. Hence, Eq. (3) is rewritten as $\dot{S} = \Delta(1/T)\dot{Q}$. Next, a heat flux is defined by $J_Q \equiv \dot{Q}/A$, where A is the cross section of the partition. In the experiment, the temperatures T' and T'' remain nearly constant within both compartments, except near the common boundary, where the change from T' to T'' occurs over a small distance l perpendicular to the partition (see Fig. 1). The product Al roughly defines a volume V in the boundary region over which the temperature changes. One can then write $\dot{S} = \Delta(1/T)VJ_Q/l$. In the limit of small l , the ratio $\Delta(1/T)/l$ becomes the gradient of inverse temperature, $\nabla(1/T)$. The ratio $\dot{S}/V$ is the rate of entropy production per unit volume, $\dot{\theta}$, in the heat transfer region. This gives, finally,

$$\dot{\theta} = \nabla(1/T)J_Q \geq 0 \quad (4)$$

Fig. 1 Two bodies of cross section A at temperatures T' and T'' and at chemical potentials μ' and μ'' are in tenuous contact. Changes in T and μ occur over a small distance/straddling the boundary. When no mass transfer occurs, the chemical potentials are irrelevant.

Heat transfer equations

The above discussion is very suggestive. The rate of entropy generation is seen to be a product of two conjugate variables, namely, a heat flux, J_Q , and a generalized force, $F_T \equiv \nabla(1/T)$; hence, schematically $\dot{\theta} = F_T J_Q \geq 0$. Note that in Eqs. (3) and (4), and with the directions indicated in Fig. 1, $\dot{\theta} > 0$ means either that $F_T > 0$, $J_Q > 0$, with $T'' < T'$, or that $F_T < 0$, $J_Q < 0$, with $T'' > T'$. In either case, heat flows from the hotter to the cooler side. When $\dot{\theta} = 0$, equilibrium prevails; J_Q and F_T both vanish. It is then plausible to claim that the heat flux is "driven" by the existence of a temperature gradient (actually, a gradient in inverse temperature).

Next, a relation between J_Q and F_T is established, which requires extrathermodynamic information, such as a microscopic transport theory or experimental considerations. Close to the equilibrium, a linear relation $J_Q = L_T F_T$ is assumed to prevail between force and flux, where L_T is a parametric function independent of J_Q or F_T . The proportionality factor is known as a phenomenological or macroscopic coefficient. The essential correctness of this very primitive approach may be checked by noting that

$$J_Q = L_T \nabla(1/T) = -(L_T/T^2) \nabla T \equiv -\kappa \nabla T \quad (5)$$

where $\kappa \equiv L_T/T^2$ is the thermal conductivity, and one recovers the *Fourier law* of heat conduction.

Transfer of energy and mass between two different regions

The above approach will now be generalized. Consider two compartments at different temperatures that contain the same material at two different mole numbers n' and n'' . The 2 units are joined and the intervening partition is rendered slightly porous, allowing the very gradual transfer of energy and of mole numbers (Fig. 1). As long as the compartmental volumes are unchanged, one can invoke the fundamental relation

$$dS = (\partial S'/\partial E')_{V',n'} dE' + (\partial S''/\partial E'')_{V'',n''} dE'' + (\partial S'/\partial n')_{V',E'} dn' + (\partial S''/\partial n'')_{V'',E''} dn'' \quad (6)$$

Since $dS = dE/T - (\mu/T)dn$, where μ is the chemical potential, and with $dE'' = -dE'$, $dn'' = -dn'$, the above may be recast as

$$dS = (1/T'' - 1/T') dE'' - (\mu''/T'' - \mu'/T') dn'' \geq 0 \quad (7a)$$

from which it follows that at equilibrium, $T' = T''$ and $\mu' = \mu''$, consistent with well-established thermodynamic principles. The earlier procedure can be extended by introducing two fluxes, namely $J_E \equiv dE''/A dt$ and $J_n \equiv dn''/A dt$, as well as two generalized forces, $F_T \equiv \Delta(1/T)/l \equiv \nabla(1/T)$ and $F_n \equiv \Delta(\mu/T)/l \equiv \nabla(\mu/T)$, appropriate for small distances, l , across the junction. Eq. (7a) thus becomes

$$\dot{\theta} = J_E \nabla(1/T) - J_n \nabla(\mu/T) \quad (7b)$$

The minus sign in this equation can also be rationalized via a sufficiency argument. To ensure that $\dot{\theta} > 0$, both terms in the expression need to be positive. Referring to Fig. 1, assume that $J_E > 0$ (i.e., energy flows left to right); to keep the first term positive it is necessary that $T'' < T'$, as before. In order to render the second term positive, one requires that $(\mu''/T'' - \mu'/T') J_n < 0$. Assume that $J_n > 0$ (particles flow from left to right), which then requires the multiplier to be negative, so that $\mu'/T' > \mu''/T''$, or $\mu'/\mu'' > T'/T'' > 1$, implying that the particle flux occurs from the region of higher chemical potential to one of lower chemical potential.

Phenomenological equations

The relation $T dS = dE - \mu dn$ is now introduced, reformulated after time differentiation as $T J_S = J_E - \mu J_n$, valid in the absence of any mechanical pressure-volume work (V' and V'' remain fixed). Using Eq. (7b), the rate of entropy production per unit volume may be written as

$$\dot{\theta} = -\frac{1}{T} \{J_S \nabla T + J_n \nabla \mu\} \geq 0 \quad (8)$$

Such a relation is of fundamental importance, in that it specifies $\dot{\theta}$ as a sum of products that involve conjugate flux-force pairs, namely, $(J_S, -T^{-1} \nabla T)$ and $(J_n, -T^{-1} \nabla \mu)$. These quantities are of great importance in the formulation of the so-called linear phenomenological equations (PEs), valid for small departures from equilibrium. These are constructed so as to relate the two fluxes J_S and J_n to the two forces $(1/T) \nabla T$ and $(1/T) \nabla \mu$ in the following linear form:

$$J_S = (L_{11}/T) \nabla T + (L_{12}/T) \nabla \mu \quad (9a)$$

$$J_n = (L_{21}/T) \nabla T + (L_{22}/T) \nabla \mu \quad (9b)$$

The minus signs have been absorbed in the L coefficients. One should note the implied superposition principle: both forces contribute to both fluxes. The L_{ij} are known as phenomenological or macroscopic coefficients; L_{11} and L_{22} connect the fluxes to their principal driving forces, while L_{12} and L_{21} give rise to interference effects that are studied in detail below.

Fig. 2 Boundary of a system, with the unit vector pointing opposite to the inward flow of energy, entropy, or mass.

Basic principles of mass, energy, and entropy balances

Mass balance equation

The very heuristic approach presented so far, while leading to correct results, ought really to be supplanted by a more rigorous (though simplified) derivation of Eqs. (9a) and (9b). One can begin with the conservation law

$$d\rho_k/dt = -\nabla \cdot J_k \quad (10)$$

wherein the total rate change in concentration ρ_k of species k within the system (Fig. 2) is given by the imbalance between the influx and outflow of species k across the boundaries; the minus sign arises because the normal unit vector in Fig. 2 faces outward.

Energy balance equations

In order to introduce relations for energy balance, one can follow the convention by changing from energy or mass per unit volume to energy per unit mass and mass fraction. This is indicated by overbars such as $\bar{u}, \bar{e}, \bar{\psi}, \bar{n}_k$, as introduced below. Further, let species k interact with a stationary external potential $\bar{\psi}_k$ (e.g., electrons in an electrostatic potential); then operating on both sides of Eq. (10) with $\sum_{(k)} \bar{\psi}_k$ and setting $\sum_{(k)} \bar{\psi}_k \rho_k \equiv \bar{\psi} \rho$, and using the vector calculus involving a scalar function a and a vector function v , $\nabla \cdot av = a \nabla \cdot v + v \cdot \nabla a$, one obtains

$$d(\rho \bar{\psi})/dt = -\nabla \cdot \sum_k \bar{\psi}_k J_k + \sum_k J_k \cdot \nabla \bar{\psi}_k \quad (11)$$

As a third step, one introduces the conservation law for total energy density $\rho \bar{u}$ (energy cannot be generated or destroyed locally):

$$d(\rho \bar{u})/dt = -\nabla \cdot J_U \quad (12)$$

The total energy density can be separated into $\bar{u} = \bar{e} + \bar{\psi}$, where $\bar{e}$ is the internal energy per unit mass. Correspondingly,

$$J_U = J_Q + \sum_k \bar{\psi}_k J_k \quad (13)$$

This nomenclature is appropriate; the net total energy flux density $\nabla \cdot J_U$ consistently reflects the performance of work, potential energy changes, and heat flows. The first two effects are subsumed in the term $\nabla \cdot \sum_k \bar{\psi}_k J_k$; the rest is contained in the net heat flux, $-\nabla \cdot J_Q$. Next, subtracting (11) from (12) and introducing Eq. (13), yields an expression for the overall rate of change of internal energy

$$d(\rho \bar{e})/dt = -\nabla \cdot J_Q - \sum_k J_k \cdot \nabla \bar{\psi}_k \quad (14)$$

This involves not only the customary divergence term but also the last term, which represents a source term that arises from the interaction of species k with the external potential $\bar{\psi}_k$.

Entropy balance relations

The entropy balance equations can be introduced by using the expression (for $dV = 0$) $TdS = dE - \sum_k \mu_k dn_k$ to write

$$T(d(\rho s)/dt) = (d(\rho \bar{e})/dt) - \sum_k \bar{\mu}_k (d\rho_k/dt) \quad (15a)$$

On insertion of Eqs. (14) and (10), one obtains

$$\frac{d(\rho \bar{s})}{dt} = \frac{1}{T} \left\{ -\nabla \cdot J_Q - \sum_k J_k \cdot \nabla \bar{\psi}_k + \sum_k \bar{\mu}_k \nabla \cdot J_k \right\} \quad (15b)$$

The above may be rearranged by repeated application of the vector identity cited earlier; standard manipulations lead to the final result

$$\begin{aligned} \frac{d(\rho\bar{s})}{dt} = & -\nabla \cdot \left\{ \left(J_Q - \sum_k \bar{\mu}_k J_k \right) / T \right\} \\ & - (1/T^2) J_Q \cdot \nabla T + (1/T^2) \sum_k \bar{\mu}_k J_k \cdot \nabla T \\ & - (1/T) \sum_k J_k \cdot \nabla (\bar{\mu}_k + \bar{\psi}_k) \end{aligned} \quad (16)$$

Although this looks complicated, it is amenable to a simple interpretation which is based on the entropy balance equation in the form $d(\rho\bar{s})/dt = -\nabla \cdot J_S + \dot{\theta}$. Comparison with Eq. (16) shows that it is appropriate to consider the quantity in curly brackets as a flux vector, so that

$$J_S = \frac{1}{T} \left(J_Q - \sum_k \bar{\mu}_k J_k \right) \quad (17)$$

is an entropy flux vector. The remaining terms are then to be identified as source terms θ in the entropy balance equation. This allows one to express the contribution of local events to the entropy generation rate as

$$\dot{\theta} = -(1/T) J_S \cdot \nabla T - (1/T) \sum_k J_k \cdot \nabla \bar{\zeta}_k \geq 0 \quad (18)$$

where the generalized chemical potential has been introduced as $\bar{\zeta} \equiv \bar{\mu} + \bar{\psi}$. For isotropic materials in the absence of external potentials, Eq. (18) reduces to Eq. (8). This establishes the proper background for constructing the PEs, Eqs. (9a) and (9b), precisely in the same manner as was done earlier.

Phenomenological equations for thermoelectric effects; Onsager's reciprocity conditions

A very important characteristic of Eqs. (9a) and (9b) is the fact that the Onsager reciprocity relations, $L_{ij} = L_{ji}$ apply to such equations, so long as conjugate flux-force pairs are employed in formulating Eqs. (9a) and (9b). For proofs, the reader is referred to the literature; a simpler version, applicable to processes under steady-state conditions, was provided by Tykody (n.d.).

Thermoelectric phenomena

Eqs. (9a) and (9b) can be specialized to characterize interactions between heat flow and electric currents in a conductor, known as thermoelectric effects; this topic has been treated elsewhere in great detail (see the "Further reading" section). Consider a rectangular bar clamped between two thermal reservoirs at different temperatures (Fig. 3). The electron flow in the conductor is established by charging external condenser plates; this cumbersome method is used here (though not in actual practice) to avoid distracting complications from leads that normally connect the sample to the current source. Using the dissipation function, Eq. (18) with $k = n$, substituting $\bar{\zeta} = \bar{\mu} - e\bar{\varphi}$ in place of $\bar{\mu}$, and then replacing the electron flux vector J_n by the current density $J = (-e)J_n$, where $-e$ is the charge on the electron and $\bar{\varphi}$ is the electrostatic potential per electron mass, the dissipation relation can be written as $\dot{\theta} = J_S \cdot (-T^{-1} \nabla T) + J \cdot (-T^{-1} \nabla (\bar{\zeta}/e))$. One can identify, from this relation, the proper fluxes and forces, so as to construct the phenomenological relations for an isotropic material (the vector notation can then be dropped):

Fig. 3 Idealized setup for detection of thermoelectric effects. The solid is clamped between two thermal reservoirs at temperatures T_1 and T_2 ; S_1 and S_2 are removable strips for thermal insulation. Current flow is activated through charging of the condenser plates C and C' .

$$J_S = -(L_{SS}/T)\nabla T + (L_{Sn}/T)\nabla(\zeta/e) \quad (19a)$$

$$J = -(L_{nS}/T)\nabla T + (L_{nn}/T)\nabla(\zeta/e) \quad (19b)$$

with $L_{nS} = L_{Sn}$. In doing so, one has also switched from $\bar{\zeta}$ to ζ , absorbing the mass factor and the minus sign in L_{Sn} and L_{nn} .

Thermoelectric transport coefficients

By imposing a variety of constraints, the above expressions can be attributed to physical significance:

- (1) Set $\nabla T = 0$ and eliminate $\nabla(\zeta/e)$ between (19a) and (19b) to obtain $J_S/J = L_{Sn}/L_{nn} = -J_S/eJ_n$; since $J_S/J_n \equiv S^*$ is the total entropy carried per electron, one obtains

$$L_{Sn}/L_{nn} = -S^*/e \quad (20)$$

Next, consider Eq. (19b) with $\nabla T = 0$. For a homogeneous sample $\nabla \mu = 0$; Eq. (19b) then reduces to $J = (L_{nn}/T) \nabla(-\phi) = (L_{nn}/T) E$, where E is the electrostatic field. Thus, one recovers

Ohm's law $J = \sigma E$, where σ is the electrical conductivity. This leads to the identification

$$L_{nn}/T = \sigma, \quad J = \sigma \nabla(\zeta/e) \quad (\nabla T = 0) \quad (21)$$

- (2) If current flow is suppressed, set $J = 0$, solve Eq. (19b) for $\nabla(\zeta/e)$, and substitute the result in Eq. (19a); this yields

$$J_S = -(1/T)[L_{SS} - L_{nS}^2/L_{nn}]\nabla T \quad (J = 0) \quad (22)$$

Now, as shown in Eq. (17), in the absence of current flow the entropy flux may be replaced by J_Q/T ; thus, one recovers *Fourier's law* of heat conduction, $J_Q = -\kappa \nabla T$, with the thermal conductivity given by

$$\kappa = L_{SS} - L_{nS}^2/L_{nn} \quad (23)$$

An additional contribution to κ arises from the lattice thermal conductivity that is not included here.

- (3) In the more general case when $J > 0$, one may still eliminate $\nabla(\zeta/e)$ between Eqs. (19a) and (19b) to obtain

$$J_S = -(S^*/e)J - (\kappa/T)\nabla T = S^*J_n - (\kappa/T)\nabla T \quad (24)$$

This shows that the total electronic entropy flux involves the entropy transport S^*J_n as well as heat transport through the motion of the electrons.

- (4) A second result arises by imposing the condition $J = 0$ and solving Eq. (19b) for

$$\nabla(\zeta/e) = (L_{nS}/L_{nn})\nabla T \equiv \alpha \nabla T \quad (25)$$

Here, one encounters a new prediction: the imposition of a temperature gradient necessarily establishes a gradient in the electrochemical potential. The proportionality factor, here designated as α , is called the *Seebeck coefficient*, or less desirably, the thermoelectric power. It is measured by connecting the ends of the sample in a temperature gradient to a voltmeter under open circuit conditions, and by determining the resulting temperature difference with, for example, a thermocouple. Comparison with Eq. (20) shows that $\alpha = -S^*/e = -\nabla(\zeta/e)/\nabla T \approx \Delta(\zeta/e)/\Delta T$. Eq. (19a) may thus be rewritten as

$$J_S = \alpha J - (\kappa/T)\nabla T \quad (26)$$

The three phenomenological coefficients may now be solved in terms of the three experimental parameters α , κ , and σ , so as to express the PEs in their final form

$$J_S = -(\sigma\alpha^2 + \kappa/T)\nabla T + \alpha\sigma\nabla(\zeta/e) \quad (27a)$$

$$J = -\sigma\alpha\nabla T + \sigma\nabla(\zeta/e) \quad (27b)$$

Eq. (27b) represents a further generalization of Ohm's law, showing how the current density is affected by the presence of a temperature gradient. The apparent differences in sign involving $\alpha\sigma$ arise because there is a corresponding sign difference in Eqs. (19a) and (19b). Thus, Onsager's relations are indeed satisfied.

A physical explanation of the *thermoelectric effect* is based on the fact that electrons at the hot end have a larger thermal velocity along the downstream direction than that associated with electrons at the cold end along the upstream direction. Consequently, a net accumulation of electrons takes place at the cold end, leaving an effective positive charge at the hot end.

Hole conductors may be treated by the same approach: a rather lengthy analysis shows that one may simply replace $-e$ by $+e$; for n -type carriers $\alpha < 0$, whereas for p -type materials $\alpha > 0$. The results otherwise carry over without change. Thermoelectric effects thus provide a means for distinguishing between n - and p -type charge transport.

Peltier and Thomson effects

Two other thermoelectric effects encountered in the literature are only briefly mentioned. The so-called *Peltier effects* arise when current is passed through an isothermal junction of two dissimilar materials (1 and 2), resulting in the production of heat. The explanation is based on Eq. (13), with $k = 1$, and ψ and $\mu \rightarrow \zeta$. An electrochemical potential is continuous across the junction; also, the current density is conserved. Hence, in passing from region 1 to region 2,

$$J_{U2} - J_{U1} = J_{Q2} - J_{Q1} = T(J_{S2} - J_{S1}) = T(\alpha_2 - \alpha_1)J \quad (27c)$$

where Eqs. (17) and (26) and $\nabla T = 0$ have been used. The *Peltier coefficient* is defined as

$$\Pi \equiv (J_{Q2} - J_{Q1})/J = T(\alpha_2 - \alpha_1) \quad (27d)$$

showing the relation between n and a . On the other hand, if current flows through a conductor with an established temperature gradient, the heat generated in line element dx (in excess of the Joule heating effect) is proportional to the current and to the temperature gradient, as expected: $\dot{Q}/dx \propto I \nabla_x T$. On introducing a proportionality factor, τ , the so-called *Thomson coefficient*, one obtains

$$J_{Qx} = \tau J_x \nabla_x T \quad (27e)$$

For an extended derivation and discussion of these effects refer to the literature.

Transport effects in magnetic fields

Now consider the effects that operate in the presence of a magnetic field, H , aligned with the z -axis. Provision is made in the sample for current and heat flow in the x and y directions (Fig. 4).

Phenomenological equations for thermomagnetic phenomena

A study of the thermoelectric and thermomagnetic interactions resulting in the presence of magnetic fields is useful. The effects introduced by the electric leads will be ignored. For this purpose the choice of $(J_s, \nabla T)$ and $(J, \nabla(\zeta/e))$ as conjugate variables is extended; the $1/T$ factors and minus signs are absorbed into the phenomenological coefficients. Three new points must be taken into account: (1) since the observed effects occur along two dimensions, $(J_s^x, \nabla_x T)$, $(J_s^y, \nabla_y T)$, $(\nabla_x(\zeta/e), J^x)$, $(\nabla_y(\zeta/e), J^y)$ are introduced as conjugate flux-force pairs. (2) For later convenience, $J_s^x, J_s^y, \nabla_x(\zeta/e), \nabla_y(\zeta/e)$ are considered as dependent variables, so that the PEs cited below appear in partially inverted form. Such a partial interchange of dependent and independent variables is a perfectly permissible mathematical step and greatly simplifies the subsequent analysis. (3) The Onsager reciprocity conditions must now be generalized to read (Casimir–Onsager relations) $L_{ij}(H) = \pm L_{ji}(-H)$, the adopted sign depending on whether or not the forces on the charged particles change sign when the magnetic field is reversed. Without loss of generality, the sequence of signs in Eq. (28a) is selected arbitrarily; the signs in the other equations are then determined by the augmented reciprocity relations. The above considerations lead to macroscopic PEs of the form

$$J_s^x = -L_{11} \nabla_x T - L_{12} \nabla_y T + L_{13} J^x + L_{14} J^y \quad (28a)$$

Fig. 4 Sample cut in a rectangular parallelepiped geometry and placed in a magnetic field H aligned with the z -axis. Current and heat pass into the solid through leads connected to R and S along x , and to T and U along y .

$$J_S^y = L_{12} \nabla_x T - L_{11} \nabla_y T - L_{14} J^x + L_{13} J^y \quad (28b)$$

$$\nabla_x(\zeta/e) = L_{13} \nabla_x T + L_{14} \nabla_y T + L_{33} J^x + L_{34} J^y \quad (28c)$$

$$\nabla_y(\zeta/e) = -L_{14} \nabla_x T + L_{13} \nabla_y T - L_{34} J^x + L_{33} J^y \quad (28d)$$

The above formulation permits a systematic investigation of the 560 possible thermoelectric and thermomagnetic effects. A selection of these is presented under a variety of headings.

Transport coefficients for thermomagnetic phenomena

- (1) $J^y = \nabla_x T = \nabla_y T = 0$: isothermal conditions are maintained along x and y and no current is allowed to flow along y . The PEs then reduce to

$$\begin{aligned} J_S^x &= L_{13} J^x & (a) \\ J_S^y &= -L_{14} J^x & (b) \\ \nabla_x(\zeta/e) &= L_{33} J^x & (c) \\ \nabla_y(\zeta/e) &= -L_{34} J^x & (d) \end{aligned} \quad (29)$$

Expression (29c) is simply a reformulation of *Ohm's law*, $J^x = \sigma_I \nabla_x(\zeta/e)$, wherein $L_{33} \equiv \rho_I$ is the isothermal resistivity of the sample. Equation (29d) describes the *isothermal Hall effect*: a current in the longitudinal direction induces a transverse gradient in the electrochemical potential; for convenience, the magnitude of the magnetic field is explicitly introduced: it can be seen that

$$\nabla_y(\zeta/e) = -(L_{34}/H) J^x H \equiv \mathfrak{R}_I J^x H \quad (30)$$

where the magnitude of the effect is characterized by the Hall coefficient $\mathfrak{R} \equiv -L_{34}/H$. Eqs. (29a) and (29b) simply relate the entropy transport along x and y to current flux along x ; L_{13} and L_{14} are determined below.

- (2) $J^y = \nabla_x T = J_S^x = 0$: open-circuit conditions are imposed and no heat flow is allowed along y ; isothermal conditions prevail along x . The PEs now reduce to

$$\begin{aligned} J_S^x &= -L_{12} \nabla_y T + L_{13} J^x & (e) \\ 0 &= -L_{11} \nabla_y T - L_{14} J^x & (f) \\ \nabla_x(\zeta/e) &= L_{14} \nabla_y T + L_{33} J^x & (g) \\ \nabla_y(\zeta/e) &= L_{13} \nabla_y T - L_{34} J^x & (h) \end{aligned} \quad (31)$$

Eq. (31f) shows that under these conditions, a longitudinal current flow produces a transverse temperature gradient; this is the so-called *Ettingshausen effect* $\nabla_y T = -(L_{14}/L_{11}H) J^x H$, with a coefficient specified by $\mathfrak{E} \equiv \nabla_y T/J^x H = -L_{14}/L_{11}H$. Insertion of (31f) into (31g) yields the expression $\nabla_x(\zeta/e) = (L_{33} - L_{14}^2/L_{11}) J^x$, which is Ohm's law under "adiabatic" conditions, with a resistivity $\rho_A = (L_{33} - L_{14}^2/L_{11})$. When (31f) is used in (31h), one obtains $\nabla_y(\zeta/e) = -[(L_{13}L_{14}/L_{11} + L_{34})/H] J^x H$, which represents the "adiabatic" Hall effect, with a corresponding coefficient $\mathfrak{R}_A \equiv -(1/H)[L_{13}L_{14}/L_{11} + L_{34}]$.

- (3) Next, set $J^x = J^y = \nabla_y T = 0$: no current flows and the temperature is uniform along y . The PEs reduce to

$$\begin{aligned} J_S^x &= -L_{11} \nabla_x T & (i) \\ J_S^y &= L_{12} \nabla_x T & (j) \\ \nabla_x(\zeta/e) &= L_{13} \nabla_x T & (k) \\ \nabla_y(\zeta/e) &= -(L_{14}/H) H \nabla_x T & (l) \end{aligned} \quad (32)$$

Under these conditions, TJ_S^x and TJ_S^y represent heat fluxes. Eq. (32i) then specifies an "isothermal" heat flux (a contradiction in terms!) $TJ_S^x = -L_{11}T \nabla_x T$ that identifies the thermal conductivity $\kappa_1 = TL_{11}$ in the absence of a transverse thermal gradient. Moreover, (32k) represents nothing other than the "isothermal" Seebeck effect, along x , for which the coefficient is given by $\alpha = L_{13}$. Furthermore, according to (32l), a T gradient along x produces a gradient in ζ along y . This is the so-called transverse Nernst effect, with a corresponding coefficient $N_I \equiv -L_{14}/H$.

- (4) Another set of constraints of interest is given by $J^x = J^y = J_S^y = 0$. These reduce the PEs to

$$\begin{aligned} J_S^x &= -L_{11} \nabla_x T - L_{12} \nabla_y T & (m) \\ 0 &= L_{12} \nabla_x T - L_{11} \nabla_y T & (n) \\ \nabla_x(\zeta/e) &= L_{13} \nabla_x T + L_{14} \nabla_y T & (o) \\ \nabla_y(\zeta/e) &= -L_{14} \nabla_x T + L_{13} \nabla_y T & (p) \end{aligned} \quad (33)$$

Eq. (33n) shows that, in this case, the temperature gradient in the longitudinal direction induces one in the transverse direction; this is known as the Righi-Leduc effect, rewritten as

$$\nabla_y T = (L_{12}/L_{11}H) H \nabla_x T \equiv MH \nabla_x T \quad (34)$$

with a corresponding coefficient $M \equiv L_{12}/L_{11}H$. A second relation of interest is found by inserting Eq. (34) into (33m) and multiplying through by T ; this yields $TJ_S^x = -T[L_{11} + L_{12}^2/L_{11}]\nabla_x T$, leading to the “adiabatic” thermal conductivity $\kappa = T(L_{11} + L_{12}^2/L_{11})$. Also, use of (34) in (33o) leads to $\nabla_x(\zeta/e) = (L_{13} + L_{14}L_{12}/L_{11})\nabla_x T$, which represents the adiabatic Seebeck effect, with a corresponding coefficient $\alpha_A = L_{13} + L_{14}L_{12}/L_{11}$. Lastly, combining (34) with (33p) yields $\nabla_y(\zeta/e) = (1/H)[-L_{14} + L_{13}L_{12}/L_{11}]H\nabla_x T$, which represents the adiabatic transverse Nernst effect, with a coefficient $N_A = (1/H)[-L_{14} + L_{13}L_{12}/L_{11}]$.

The above procedure may be applied repeatedly to obtain other galvano-thermomagnetic effects; these are left to the reader to explore.

Identification of phenomenological coefficients

The principal inference of the discussion so far is that the various parameters L_{ij} of the PEs in Eqs. (28a)–(28d) can be rewritten in terms of experimentally determined parameters. These are:

$$\begin{aligned} L_{33} &= \rho_I \quad (\text{q}), \quad L_{34} = -\mathfrak{R}_I H \quad (\text{r}) \\ L_{11} &= \kappa_I/T \quad (\text{s}), \quad L_{13} = \alpha_I \quad (\text{t}) \\ L_{14} &= -N_I H \quad (\text{u}), \quad L_{12} = \kappa_I M_I H/T \quad (\text{v}) \end{aligned} \quad (35)$$

The subscript I has been introduced to indicate isothermal conditions, that is, $\nabla_y T = 0$. By inserting (35) into the PEs, a complete description of the galvano-thermomagnetic effects that are observable in the rectangular parallelepiped geometry of Fig. 4 has been obtained.

Transport in two-band (electron–hole) conductors

In conclusion, a limited set of galvano-thermomagnetic phenomena for a material in which both holes and electrons contribute to the conduction process can be considered. For this purpose, it is necessary to use the PEs in uninverted form, so that the partial currents can be summed to form the total current. Specializing to the case $J^y = \nabla_x T = \nabla_y T = 0$, the expressions involving J_S^x and J_S^y are not needed. In an obvious notation, the PEs for electron and hole conduction become, with due regard to the Casimir–Onsager conditions,

$$J_-^x = \Gamma_1 \nabla_x(\zeta/e) + \Gamma_2 \nabla_y(\zeta/e) \quad (36a)$$

$$J_-^y = -\Gamma_2 \nabla_x(\zeta/e) + \Gamma_1 \nabla_y(\zeta/e) \quad (36b)$$

$$J_+^x = \Gamma_3 \nabla_x(\zeta/e) + \Gamma_4 \nabla_y(\zeta/e) \quad (36c)$$

$$J_+^y = -\Gamma_4 \nabla_x(\zeta/e) + \Gamma_3 \nabla_y(\zeta/e) \quad (36d)$$

Use of constraints to identify transport coefficients

Consider first the one-band, n -type semiconductor, by setting $\Gamma_3 = \Gamma_4 = 0$. If $J_-^y = 0$ as well, (36a) and (36b) can be solved for:

$$J_-^x = [(\Gamma_1^2 + \Gamma_2^2)/\Gamma_1] \nabla_x(\zeta/e) \equiv \sigma_n \nabla_x(\zeta/e) \quad (37a)$$

which immediately identifies the n -type conductivity σ_n . One can also write

$$J_-^x = [(\Gamma_1^2 + \Gamma_2^2)/\Gamma_2] \nabla_y(\zeta/e) \quad (37b)$$

$D \equiv [(\sigma_n + \sigma_p)^2 + (H\sigma_n\sigma_p)^2(\mathfrak{R}_n + \mathfrak{R}_p)^2]/\sigma_n\sigma_p$ are electrical conductivity of electrons and holes, respectively; $\mathfrak{R}_n, \mathfrak{R}_p$ are Hall coefficients of electrons and holes; ρ is the electrical resistivity; α_n, α_p are the Seebeck coefficient of electrons and holes, respectively; κ_n, κ_p are the thermal conductivity of electrons and holes, respectively; N_n, N_p are the transverse Nernst coefficients of electrons and holes, respectively; and H is the applied magnetic field. Note that $\alpha_n = -|\alpha_n|$, $\mathfrak{R}_n = -|\mathfrak{R}_n|$ are negative, while $\sigma_n, \sigma_p, N_n, N_p$ are positive; hence $\mathfrak{R}$ and α tend to be small except in large applied magnetic fields.

which introduces the Hall coefficient for electrons as

$$\mathfrak{R}_n H = \Gamma_2/(\Gamma_1^2 + \Gamma_2^2) \quad (38)$$

Eqs. (37a) and (38) yield the result $\Gamma_2/\Gamma_1 = \sigma_n H \mathfrak{R}_n \equiv X_n$.

On elimination of Γ_2 using (38), $\Gamma_1 = \sigma_n/(1 + X_n^2)$. Similarly, $\Gamma_2 = \sigma_n X_n/(1 + X_n^2)$. Analogous operations for a hole conductor yield the results $\Gamma_4/\Gamma_3 = \sigma_p H \mathfrak{R}_p \equiv X_p$, $\Gamma_3 = \sigma_p/(1 + X_p^2)$, $\Gamma_4 = \sigma_p X_p/(1 + X_p^2)$. The total current density is then given by

$$J^x = J_-^x + J_+^x = \Gamma_a \nabla_x(\zeta/e) + \Gamma_b \nabla_y(\zeta/e) \quad (39a)$$

$$J^y = J_-^y + J_+^y = -\Gamma_b \nabla_x(\zeta/e) + \Gamma_a \nabla_y(\zeta/e) \quad (39b)$$

with $\Gamma_a \equiv \Gamma_1 + \Gamma_3$, $\Gamma_b \equiv \Gamma_2 + \Gamma_4$. Setting $J^x = 0$ and eliminating either $\nabla_y(\zeta/e)$ or $\nabla_x(\zeta/e)$ from Eqs. (39a) and (39b). One finds

Table 1 Galvano-thermomagnetic effects for a two-band n - p conductor in a magnetic field.

Electric resistivity:	$\rho = [(\sigma_n + \sigma_p) + H^2 \sigma_n \sigma_p (\sigma_n \mathfrak{R}_n^2 + \sigma_p \mathfrak{R}_p^2)]/D$
Hall coefficient:	$\mathfrak{R} = [\mathfrak{R}_n \sigma_n^2 + \mathfrak{R}_p \sigma_p^2 + (H \sigma_n \sigma_p)^2 (\mathfrak{R}_n \mathfrak{R}_p) (\mathfrak{R}_n + \mathfrak{R}_p)]/D$
Seebeck coefficient:	$\alpha = [(\sigma_n + \sigma_p)(\sigma_n \alpha_n + \sigma_p \alpha_p) + (H \sigma_n \sigma_p)^2 (\mathfrak{R}_n + \mathfrak{R}_p)(\mathfrak{R}_n \alpha_p + \mathfrak{R}_p \alpha_n) + H^2 \sigma_n \sigma_p (N_n - N_p)(\mathfrak{R}_n \sigma_n - \mathfrak{R}_p \sigma_p)]/D$
Thermal conductivity:	$\kappa = \kappa_n + \kappa_p + (T/D) \left\{ \sigma_n \sigma_p (\sigma_n + \sigma_p) (\alpha_n - \alpha_p)^2 - (N_n - N_p) (\sigma_n \sigma_p H^2) \right\} \times [(\sigma_n + \sigma_p)(N_n - N_p) - 2 \sigma_n \sigma_p (\mathfrak{R}_n + \mathfrak{R}_p) (\alpha_n - \alpha_p)]$

Table 2 Galvano-thermomagnetic effects to the limit of small applied magnetic fields: $H \rightarrow 0$.

$\sigma = \sigma_n + \sigma_p$,	$\alpha = \frac{\alpha_n \sigma_n + \alpha_p \sigma_p}{\sigma_n + \sigma_p}$
$\mathfrak{R} = \frac{\mathfrak{R}_n \sigma_n^2 + \mathfrak{R}_p \sigma_p^2}{(\sigma_n + \sigma_p)^2}$,	$\kappa = \kappa_n + \kappa_p + \frac{T \sigma_n \sigma_p (\alpha_n - \alpha_p)^2}{\sigma_n + \sigma_p}$

$$J^x = \frac{\Gamma_a^2 + \Gamma_b^2}{\Gamma_a} \nabla_x (\zeta/e) \quad \text{or} \quad \sigma = \frac{\Gamma_a^2 + \Gamma_b^2}{\Gamma_a} \quad (40a)$$

$$J^x = \frac{\Gamma_a^2 + \Gamma_b^2}{\Gamma_b} \nabla_y (\zeta/e) \quad \text{or} \quad \frac{1}{H\mathfrak{R}} = \frac{\Gamma_a^2 + \Gamma_b^2}{\Gamma_b} \quad (40b)$$

The last step consists in replacing Γ_a, Γ_b by $\Gamma_1, \dots, \Gamma_4$, and introducing $X_n, X_p, \sigma_n, \mathfrak{R}_n H, \sigma_p, \mathfrak{R}_p H$. The steps are elementary but tedious. The results are listed in Tables 1 and 2.

A similar procedure may be used to determine the Seebeck coefficient and thermal conductivity of a two-band conductor. For detailed derivations, the reader is referred to the literature. The results are again displayed in Tables 1 and 2.

See notes in Table 1.

The principal points to be noted are (1) that the results are model-independent, and (2) that the contribution from electrons and holes in general are not simply additive.

Conclusion

This article has focused on the thermodynamic representation of irreversible effects as applied to electron transport phenomena in conductors. The advantage of this approach is its generality (aside from specific restrictions mentioned earlier); it does not depend on the adoption of a specific model for electron transport. The disadvantage is that the phenomenological parameters and transport coefficients remain unspecified. One may now invoke the microscopic transport theory to evaluate these quantities from first principles, at least in certain degrees of approximation, but this is a rather lengthy procedure beyond the scope of the present article. For additional information readers are encouraged to consult the literature that now extends to over 140 years and provides a text book example of a thoroughly explored research field.

Abstract

In the analysis of phase transformations, the thermodynamic evaluation of phase stability and the hierarchy of equilibrium conditions is essential in understanding the response of materials to changes in temperature, pressure, composition and size scales. For phase transformations driven by undercooling, overpressure or supersaturation metastable phases can develop during the phase selection involved in competitive nucleation and growth. During the early stage of reaction constrained equilibrium and nanoscale size effects can alter the relative phase stability. These important features of phase transformations are treated in terms of the governing thermodynamic relationships. Current developments are highlighted for the computational modeling of phase transformations and phase stability.

Key points

- Advances in analysis

Introduction

A central focus of phase transformation thermodynamics is the examination of relative phase stability. Under most conditions, phase stability is considered in terms of the response of a material to changes in temperature, pressure, composition and size scale. The changes are often applied rapidly in order to establish undercoolings, overpressures and supersaturations, that place the initial stable phase in a metastable (or energized) condition. The relaxation of a metastable state to the stable state can proceed through a succession of various other metastable states, but the rate of the relaxation processes is usually limited by diffusional kinetics for thermally activated reactions (Turnbull, 1981). In general, it is often useful to identify also the rate limiting stage of a phase transformation reaction as either the nucleation or the growth stage since the thermodynamic analysis for each stage can be different (Christian, 1975; Porter and Easterling, 1992).

[☆]*Change History:* September 2022. JH Perepezko updated the text. Section 5 Advances in Analysis has been added.

The essential thermodynamics that governs the relative phase stability for phase transformation reactions can be represented in analytical expressions for the Gibbs free energy as a function of temperature, pressure, composition and size scale and other appropriate variables (Lupis, 1983; Gaskell, 1995; Hillert, 1998). The relationships can also be presented in a graphical form that can facilitate the interpretation and visualization of the free energy changes, the metastable phase options and various reaction pathways that often occur in kinetic competition.

A useful concept for the study of phase transformation processes is the distinction between closed and open system processes (Martin and Bellon, 1984). In a closed system, an energized state is achieved through a rapid temperature, pressure or composition change to create a certain level of undercooling or supersaturation (i.e., a metastable state), which then releases the excess free energy during relaxation toward the equilibrium stable state. With an open system, the energized state is often attained by a continuous incremental excess energy input to an initial state through the incorporation of excess lattice defects or solute on a localized spatial scale and time interval that is short compared to the relaxation time so that the relaxation process can be influenced by external factors. Regardless of the type of phase transformation or synthesis method, there are common themes in the phase stability. The fundamental issues include the phase selection during the initial synthesis and the phase stability after synthesis and during subsequent treatment.

In order to treat the basic issues in phase stability within the limited coverage that is available, some of the key points are examined by considering selected thermodynamic relations for macroscopic systems and their modification for high interfacial area nanoscale systems. A central issue is the free energy change (i.e., driving free energy) associated with a phase transformation reaction. As a means of illustrating the use of the relevant thermodynamic concepts some examples are considered for the evaluation of the driving free energy and the ranking of different levels of metastability.

Phase stability thermodynamics

Equilibrium

There are a number of essentially equivalent approaches to describe thermodynamic equilibrium. For a closed system, the general conditions for equilibrium are represented by a maximum in entropy, S or a minimum in free energy, G with respect to a system variable, z where z can be a variable such as pressure, P , temperature, T or V as given by

$$dS/dz = 0 \text{ and } d^2S/dz^2 \leq 0 \quad (1)$$

or

$$dG/dz = 0 \text{ and } d^2G/dz^2 \geq 0 \quad (2)$$

These conditions prevail for either local minima that represents a metastable equilibrium or for an absolute minima that holds for a stable equilibrium as illustrated in Fig. 1.

Pure components

In the analysis of relative phase stability and the driving forces for different phase transformation reactions the Gibbs free energy, G , is the main quantity of interest. By definition, $G = H - TS = E + PV$ where H is the enthalpy, E is the internal energy, and PV represents the system work (Lupis, 1983; Gaskell, 1995; Hillert, 1998). For reactions between two phases, the free energy change is the difference, $\Delta G = \Delta H - T\Delta S$. For example, during solidification of a liquid, $G_s - G_l = (H_s - H_l) - T(S_s - S_l)$ or $\Delta G_f = \Delta H_f - T\Delta S_f$. At equilibrium, $\Delta G_f = 0$ so that $\Delta S_f = \Delta H_f/T_m$. If ΔS_f is taken as independent of T (i.e., neglecting the small heat capacity correction), then $\Delta G_f = \Delta H_f[1 - T/T_m] = \Delta H_f[T_m - T]/T_m = \Delta H_f\Delta T/T_m$ so that the driving free energy (i.e., driving force) available to accomplish the reaction is proportional to the undercooling, ΔT . The dependence of the molar free energy on temperature is illustrated in Fig. 2 for a liquid, a stable α phase and a metastable β phase where it is evident that the formation of the metastable β phase requires a minimum liquid undercooling below the stable α phase melting point of $\Delta T = T_m^\alpha - T_m^\beta$.

From the second law of thermodynamics several differential relations can be developed (i.e., Maxwell relations). The relation for the Gibbs free energy for a single phase is.

Fig. 1 Schematic comparison of metastable (i.e., local) and stable (i.e., absolute) equilibrium.

Fig. 2 Free Energy as a function of temperature for a single component. The melting point of the stable α phase T_m^α and the metastable β phase T_m^β is indicated.

$$dG = VdP - SdT \quad (3)$$

For the liquid-solid case at equilibrium, $dG = 0$ and.

$$V_s dP - S_s dT = V_l dP - S_l dT. \quad (4)$$

Or

$$(dP/dT)_{eq} = [S_s - S_l] / [V_s - V_l] = \Delta S_f / \Delta V_f = [\Delta H_f / (\Delta V_f T_m)] \quad (5)$$

which is the Clapeyron equation for the pressure dependence of the melting point. When Eq. (3) is applied to other two-phase coexistence such as solid-liquid, solid-vapor and liquid-vapor equilibrium, the pressure-temperature phase diagram for a single component is developed as shown in Fig. 3. The solid lines represent the two-phase coexistence conditions where there is one degree of freedom according to the phase rule (i.e., $p + f = c + 2$ where p = the number of phases, f = the number of degrees of freedom and c = the number of components). The lines intersect at an invariant triple point where $f = 0$. It is useful to note that $(\partial G / \partial T)_P = -S$ and $(\partial G / \partial P)_T = V$ as illustrated in Fig. 2.

Classification of phase transformations

The pure component reactions that are depicted in Fig. 3 are often classified as first order phase transformations. At T_e , the equilibrium transformation temperature, $G^\alpha = G^\beta$, but the slopes are different (i.e., $dG^\alpha/dT \neq dG^\beta/dT$). This gives rise to a discontinuity in S, V and H at T_e and a singularity in heat capacity, $C_p = T(dS/dT) = T(d^2G/dT^2)$ as illustrated in Fig. 4.

During a second order phase transformation S, V and H are continuous at the transformation temperature or critical temperature, T_c (i.e., there is no latent heat), but there is a discontinuity in heat capacity as indicated in Fig. 4. Second order phase transformations are often associated with electronic effects such as the paramagnetic/ferromagnetic transition, but they can also be observed for certain order-disorder changes in alloys (Soffa and Laughlin, 1989).

The distinction between first and second order phase transformations also has an impact on the presentation of the equilibria in a phase diagram and the progress of a phase transformation (Porter and Easterling, 1992). For example, long range ordering of unlike atoms in a crystal lattice develops due to an attractive interaction between unlike atoms. During a first order reaction, the development of an ordered atomic arrangement initiates at separate regions as the temperature falls below T_e as shown in Fig. 5. A sharp interface separates the transformed (i.e., ordered) regions and the untransformed (i.e., disordered) regions. Across this interface there is a jump in the long-range order parameter, η that varies from zero for a random arrangement to unity for a perfectly ordered arrangement. The coexistence at T_e is represented on the phase diagram as a two-phase field between the ordered and the disordered phase. In contrast, during a second order reaction, the development of an ordered arrangement initiates throughout the volume at the critical temperature, T_c and develops with increasing values of η progressively as the temperature is lowered below T_c . There is no two-phase coexistence of an ordered and a disordered phase so that the phase diagram does not display a two-phase field. Instead, the phase diagram shows the locus of T_c as a function of composition.

Fig. 5 Schematic illustration of the temperature dependence of η and the phase diagram characteristics for (a) first-order and (b) second-order phase transformations.

Alloy solutions

For alloy solutions, the chemical terms for the free energy are included by adding the partial molar free energy for each component, i or j to Eq. (3) as

$$dG = VdP - SdT + (\partial G/\partial n_i)_{T,P,n_j} dn_i + (\partial G/\partial n_j)_{T,P,n_i} dn_j, \quad (6)$$

where n is the number of moles. The partial molar free energy represents the chemical potential, μ_i , that is defined as

$$(\partial G/\partial n_i)_{T,P,n_j} = \mu_i = \mu_i^0 + RT \ln a_i, \quad (7)$$

where μ_i^0 is the standard state chemical potential, R is the gas constant and a_i is the activity that is the product of an activity coefficient, γ_i and the mole fraction, X_i (note that for a binary solution $X_i + X_j = 1$). For an alloy solution at constant T and P with a given composition X_0 in an A-B system the molar free energy is.

$$G = (1 - X_0)\mu_A + X_0\mu_B \quad (8)$$

and as indicated in Fig. 6, Eq. (8) describes the tangent to the G vs X_B curve at X_0 . For reaction between two coexisting solution phases such as liquid and solid in an alloy with overall composition X_0 .

$$\Delta G = (1 - X_0)(\mu_A^s - \mu_A^l) + X_0(\mu_B^s - \mu_B^l), \quad (9)$$

At equilibrium, $\Delta G = 0$ so that $(\mu_A^s = \mu_A^l) = (\mu_B^s = \mu_B^l)$ and the two phases share a common tangent.

For the examination of interactions in solutions it is often useful to represent the free energy change for mixing of pure components to form a solution, ΔG_m , in terms of an enthalpy of mixing, ΔH_m and a mixing entropy, ΔS_m . The simplest model is based upon an ideal solution where there are no nearest neighbor interactions so that $\Delta H_m = 0$ and $\gamma_i = 1$ and the ideal entropy of mixing is given by

$$\Delta S_m = -R[(1 - X_B) \ln (1 - X_B) + X_B \ln X_B]. \quad (10)$$

Most real solutions are not ideal. When the departure from ideal behavior is modest so that the molar volume change upon mixing to form a solution is negligible, the enthalpy of mixing can be represented in terms of the nearest neighbor pairwise interaction energies E_{AA} , E_{BB} and E_{AB} as

$$\Delta H_m = ZN_a X_A X_B [E_{AB} - 0.5(E_{AA} + E_{BB})] \quad (11)$$

or

$$\Delta H_m = \Omega X_A X_B, \quad (12)$$

where Z is the lattice coordination number, N_a is the Avogadro number and $\Omega = ZN_a[E_{AB} - 0.5(E_{AA} + E_{BB})]$ is a constant for a regular solution. The entropy of mixing is given by the ideal solution expression (Eq. 8) to yield.

$$\Delta G_m = \Delta H_m - T \Delta S_m = \Omega X_A X_B + RT[(1 - X_B) \ln (1 - X_B) + X_B \ln X_B]. \quad (13)$$

The composition dependence of ΔG_m is shown in Fig. 7 for different values of Ω and temperature. For exothermic solutions, $\Omega < 0$ and mixing results in a free energy decrease at all temperatures. In this case the preference for unlike atom pairings results in a tendency for the development of ordering in the solid solution. When $\Omega > 0$, however, the behavior can change with temperature. At high temperatures $T\Delta S_m$ is greater than ΔH_m for all compositions and the free energy curve has a positive curvature at all points. At low temperatures however, $T\Delta S_m$ can be smaller than ΔH_m and ΔG_m displays a change in curvature with a negative curvature near the pure component compositions that changes to a positive curvature (i.e., unstable solutions) in the central composition range. The positive value of Ω indicates a preference for pairings of like atoms and results in a tendency for the development of clustering in the solid solution.

Fig. 6 Schematic free energy vs composition diagrams for a binary alloy as (a) a single phase liquid solution with the component chemical potentials μ_A^L and μ_B^L determined by the pure component intersections with the tangent to the G vs X_B curve at X_0 and as (b) a two-phase liquid-solid equilibrium with common tangent points at X_S and X_L .

Fig. 7 The influence of temperature and ΔH_m on ΔG_m .

Fig. 8 Schematic phase diagram (a) and free energy vs composition diagram (b) for a binary alloy that exhibits a eutectic reaction: $L \rightarrow \alpha + \beta$. The relationship between the phase boundaries on the phase diagram and the common tangents is illustrated for a temperature T_1 where both a stable $\alpha + \beta$ and the metastable $L + \alpha$ and $L + \beta$ two-phase equilibria could occur for different kinetic conditions. The location of the T_0 points are indicated by filled circles.

The composition dependence of ΔG_m yields a concave curve when $\Delta H_m < 0$ as illustrated in Fig. 6a. In addition, in Fig. 6b, the equilibrium condition of the equality of the chemical potential for each component in the coexisting phases is illustrated by the common tangent construction. The various phase equilibria that are defined by a collection of free energy vs compositions diagrams at different temperatures are the basis of the equilibrium phase diagram. As demonstrated in the schematic diagram in Fig. 8, the common tangent points on the free energy vs composition diagram define the tie lines between coexisting phases at each temperature on the phase diagram. Within the two-phase regions defined by the common tangents the free energy curves intersect. The point of intersection defines the limit to partitionless transformation. For liquid compositions to the left of the intersection (i.e., A-rich compositions) there is a free energy decrease for a composition invariant or partitionless solidification. For liquid

Fig. 9 Alloys between the spinodal points are unstable and can decompose into two coherent phases α_1 and α_2 without overcoming an activation energy barrier. Alloys between the miscibility gap and the spinodal are metastable and can decompose only after nucleation of the other phase.

compositions to the right of the intersection a partitionless solidification is impossible since the free energy would increase. The locus of the intersection points as a function of temperature is often called a T_0 curve (Hillert, 1998).

When $\Delta H_m > 0$, the composition dependence of ΔG_m displays a change in curvature as noted in Fig. 7 and presented in more detail in Fig. 9. As shown in Fig. 9, the phase diagram for a solution with $\Delta H_m > 0$ exhibits a miscibility gap at low temperature where a homogeneous solution, α decomposes into two solutions α_1 and α_2 . Due to the change in curvature of the G vs X_B curve, there is a fundamental change in the stability of solutions within the miscibility gap and a resultant change in the mechanism of the decomposition mechanism (Cahn, 1961, 1968). For example, solutions with compositions within the range between X_1 and the turning point (i.e., where $d^2G/dX_B^2 = 0$) or between the turning point and X_2 are metastable since $d^2G/dX_B^2 > 0$. This signifies that fluctuations in composition that are necessary to accomplish the decomposition reaction result in an increase in free energy that represents a barrier to the reaction. For these solutions, a nucleation process is required to initiate the decomposition reaction. In contrast, solutions with compositions between the turning points are unstable since $d^2G/dX_B^2 < 0$. In this case fluctuations in composition are spontaneous since they lead to a reduction in free energy. The demarcation between metastable and unstable solutions within the miscibility gap is represented by the spinodal curve that refers to the locus of temperatures and compositions where $d^2G/dX_B^2 = 0$.

Phase transformation energetics

An important application of the thermodynamic description of phase stability is the representation of the free energy change that accompanies a phase transformation (i.e., the driving free energy). A change of phase requires a departure from equilibrium as the system develops a supersaturation or an undercooling that represents the driving free energy as indicated in Fig. 10. For a dilute

Fig. 10 Schematic illustration for the development of a supersaturation $[X_0/X_N]$ as an α phase alloy of composition X_0 is undercooled by an amount ΔT below the α phase solvus boundary. During the initial formation of a β phase precipitate, the maximum driving free energy for nucleation, ΔG_N is given by the parallel tangent construction.

solution where the activity can be represented by the mole fraction, the free energy change associated with a precipitation reaction where the α phase composition changes from X_0 to X_α as pure β develops at temperature T_1 is given by

$$\Delta G = RT_1 \ln (X_0/X_\alpha). \quad (14)$$

Since the solvus phase boundary composition, X_s , may be represented as

$$X_s = \exp(\Delta S_s) \exp(-\Delta H_s/RT) \quad (15)$$

where ΔS_s is the entropy for solution and ΔH_s is the enthalpy of solution, the free energy change for precipitation can be expressed as

$$\Delta G = \Delta H_s \Delta T/T_s \quad (16)$$

demonstrating again that a supersaturation can be expressed in terms of an equivalent undercooling. It should be noted that the expressions in Eqs. (12) or (14) refer to the overall ΔG for the reaction, $\alpha(X_0) \rightarrow \alpha(X_\alpha) + \beta(X_\beta)$. During the initial nucleation stage when a small quantity of β forms, the α matrix composition is not changed much from the X_0 value. In this case the maximum driving free energy for nucleation of β , ΔG_N is given by the separation between the tangent to the G_α curve at X_0 and a parallel tangent to the G_β curve as illustrated in Fig. 10. The tangent to the G_β curve occurs at the composition X_N that is the favored composition for a β nucleus (i.e., the composition with the largest driving free energy) (Hillert, 1998).

Similarly, for a phase transformation involving the decomposition of an initial phase such as the liquid with composition X_E in Fig. 8 into two phases such as α of composition X_α and β of composition X_β the ΔG for reaction can be evaluated from Eq. (8). The free energy change is given by the separation between the tangent to the G_L curve at X_E and the common tangent to the G_α and G_β curves as

$$\Delta G = (\mu_\alpha^B - \mu_L^B)X_E + (\mu_\alpha^A - \mu_L^A)(1 - X_E) \quad (17)$$

Phase stability hierarchy

Nucleation—Controlled reactions

Throughout the analysis of transformation behavior, it is commonly recognized that nucleation control is an important part of the initial stage of a reaction. Under nucleation control a strong temperature dependence of the product phase selection and number density can develop and lead to a nanoscale microstructure. Nucleation limitations in diffusion reactions, especially those involved in reactive diffusion also represent a form of nucleation control that is important in nanostructure synthesis. In terms of alloy metastability, nucleation control is important in allowing access to metastable states. In effect, the observation of nucleation control is directly related to the factors that promote the development of large undercooling or supersaturation, enable the expression of kinetic transitions through competitive phase selection and result in the refinement of the product size to the nanoscale level (Boettinger and Perepezko, 1993).

Competitive phase selection and metastability

A common theme in the development of new microstructural options by phase transformations is the occurrence of metastable structural states. Often, the reactions that occur during the freezing of undercooled liquids or during other rapid transformations are viewed as non-equilibrium processes (Boettinger and Perepezko, 1993; Perepezko and Boettinger, 1983). However, it is also evident that some of the departures from full equilibrium can be considered in terms of different levels of metastability. In fact, a hierarchy of equilibrium can be identified based upon the severity of the kinetic constraints that affect the capability of a material to relax toward full equilibrium during processing. As the rate of reaction becomes faster, kinetic constraints that can arise from nucleation and growth limitations associated with an equilibrium product phase formation can develop and can expose alloy metastability that often coincides with nanostructure synthesis. For the suppression of the equilibrium phase or the formation of a kinetically favored metastable phase, it is still possible to analyze reactions in terms of a metastable equilibrium that is used locally at interfaces. The transition from stable to metastable equilibrium is illustrated in Fig. 11 where the kinetic suppression of an equilibrium γ phase (Fig. 11a) yields a metastable eutectic involving the α and β phases. Moreover, it is expected that the application of the appropriate local equilibrium can be used when the processing involves nanoscale structures. Under extreme conditions, loss of interfacial equilibrium for either a stable or metastable phase can develop when even interfacial relaxation becomes too slow. With the loss of interfacial equilibrium, thermodynamics can still be used to restrict the possible range of compositions that can exist at an interface at various temperatures since the selection must yield a net reduction in the free energy of the system. One way to represent the thermodynamic restrictions is based upon the application of T_0 curves which represent the locus of temperatures and compositions where the free energies of two phases are equal as illustrated in Fig. 6 for liquid and solid phases and thus define the limiting condition for partitionless transformation. For example, as interfacial equilibrium is lost, the liquidus and solidus boundaries in Fig. 11b collapse to the T_0 curves. With isomorphous systems that exhibit complete solubility the T_0 curve is continuous with composition (Fig. 11c) while for alloys based upon components with different structures each crystal phase has a T_0 curve (Fig. 11d). At temperatures and compositions above the T_0 curves solute partitioning is required for solidification (Fig. 11d). Because of the diffusional constraint due to solute partitioning, a crystallization reaction can be inhibited by quenching

Fig. 11 Schematic illustration of some of the levels in the hierarchy of equilibrium. The equilibrium phase diagram of a system with an intermediate phase is given in (a). Included are the metastable extensions of the liquidus and solidus curves for the primary solution phases (dashed). Solidification under metastable equilibrium conditions can result in a bypassing of the intermediate phase to yield a metastable eutectic phase diagram between α and β . The T_0 curves for the primary solutions are included in (b). The extensions of these curves to temperatures below the metastable eutectic are indicated as dashed curves. In (c) the primary phases have the same structure so that a complete single phase solid solution is formed. If the primary phases have different crystal structures and low mutual solubility, then the T_0 curves might not intersect. Such a situation favors glass formation in the composition range where the T_g curve is greater than the T_0 curves in (d).

to promote glass formation. Within the overall hierarchy of stability the systematic examination of the different levels of kinetic constraints can provide useful insight into the thermodynamic analysis of alloy metastability and phase selection.

Constrained equilibrium

There are a number of important cases where phase transformation reactions proceed under various constraints that can involve externally imposed conditions or internally generated limitations. A common example is the development of a metastable phase because of favorable nucleation and growth kinetics compared to the stable phase. This is a kinetically constrained equilibrium. Another kinetically constrained equilibrium can develop in alloys where one component exhibits a significantly higher diffusivity than the other components. This is commonly observed in alloy steels where the high diffusivity component is an interstitial component such as carbon and the other slow diffusivity components are substitutional species. The high diffusivity component is able to establish an equality of the chemical potential in the coexisting phases before the slow diffusivity components. This is called paraequilibrium (Hillert, 1998). Of course, since paraequilibrium is constrained kinetically, it will dissipate with time as the alloy approaches the stable equilibrium.

During the initial stages of a phase transformation reaction in the solid state or during deposition from the vapor, it is often observed that the product phase exhibits an epitaxial crystallographic relationship with the transforming phase or the substrate involving the interfacial matching of lattice planes and directions. The appearance of a crystallographic matching results in a reduction of the interfacial energy that in turn yields favorable nucleation kinetics. However, the matching is rarely perfect so that there remains a residual interfacial strain. The resulting elastic strain energy represents another component to the free energy. With progress of the reaction, the product phase grows and there is a loss of coherency and elastic strain energy.

The elastic strain energy is usually not partitioned equally between the transforming and product phase so that the constraint of lattice matching across the interphase interface alters the phase equilibrium. This constrained equilibrium is designated as coherent equilibrium (Cahn and Larchi, 1984; Johnson, 1999). Because the level of elastic strain energy depends on the volume, the

influence of coherent equilibrium is a function of composition in the two phase region (i.e., relative amounts of phases). This yields new behavior that is beyond the scope of coverage in this discussion.

Thermodynamics of nanoscale systems

The nanoscale is often reported as a linear dimension but the important interfacial effects should be considered in terms of the interfacial area per unit volume (A/V). For example, for a sphere: $A/V = 3/r = 3 \times 10^7 \text{ m}^{-1}$ for $r = 100 \text{ nm}$.

This is significant!

Interfacial effects can be included in the free energy as

$$dG = VdP - SdT + \sum \mu_i dn_i + \sum \sigma_i dA_i, \quad (18)$$

where σ_i is the interfacial energy and A_i is the interfacial area.

The increment in free energy due to interfaces (Garvie, 1978; Trivedi, 1999) is represented by the Gibbs-Thompson relation in terms of the interface curvature κ , that is determined by the principal radii, r_i , as

$$\Delta G = \kappa \sigma = (r_1^{-1} + r_2^{-1}) \sigma \quad (19)$$

For a sphere, $\Delta G = 2\sigma/r$. The effect of curvature on the melting point and the relative phase stability is indicated in Fig. 12 where the dependence of melting point on curvature can be expressed from Eqs. (3) and (13) as

$$T_m(r) = T_m(\infty) - 2\sigma_{SL}V_m/(r\Delta S_f). \quad (20)$$

There are two key points that are illustrated in Fig. 12. First, the macroscopic melting points for the α and β phases i.e., $T_{m\alpha}$ and $T_{m\beta}$ decrease with increasing curvature. Secondly, the β phase that is metastable for macroscopic sizes becomes the stable phase with respect to α phase at high curvature values. Furthermore, the phase stability relations for a macroscopic scale system can be modified in different ways depending on the relative magnitude of σ for each phase for a nanostructured system. As illustrated in Fig. 13, when $\sigma_\alpha < \sigma_\beta$, the stability of α is enhanced at the nanoscale. However, when $\sigma_\beta < \sigma_\alpha$, there is a reversal of phase stability at the nanoscale. There are a number of examples of the reversal in relative phase stability when the size scale changes from macroscopic to nanostructured.

The excess free energy due to curvature that acts to control the relative phase stability in nanoscale materials also acts to modify other thermodynamic behavior. For example with the same analysis that was applied to express the curvature dependence of the melting point, the dependence of the solubility may be represented in terms of particle size. This behavior is illustrated in Fig. 14 where it is evident that the increase in chemical potential with decreasing particle size will act to drive a diffusive flux between neighboring particles in a particle size distribution such as that produced by a precipitation reaction (Porter and Easterling, 1992). An important consequence of the interparticle transport is the dissolution of the finest particles along with a concomitant increase in

Fig. 12 Schematic illustration of the influence of curvature ($1/r$) on the melting point of the α phase and the β phase and on the relative phase stability when $[\sigma_{\alpha L}V_m/\Delta S_f^2 > \sigma_{\beta L}V_m/\Delta S_f^2]$.

Fig. 13 Schematic Illustration of the modification of the stability of the α phase at the nanoscale. (a) when $\sigma_\alpha < \sigma_\beta$, there is an enhancement of α phase stability; (b) when $\sigma_\alpha > \sigma_\beta$, there is a reversal of phase stability between the α phase and the β phase.

Fig. 14 Schematic free energy vs composition diagram demonstrating the influence of interface curvature of a β phase particle on the solubility.

the average particle size in the distribution (Christian, 1975). This coarsening behavior is central to the kinetic stability of a nanoscale microstructure.

A useful perspective on the different phase transformation reactions can be developed by considering the relative magnitudes of the driving free energies associated with each of the reactions. A partial summary of the representative magnitudes for the driving free energies for a selection of reactions is presented in Table 1. The listings in Table 1 indicate that for typical processes involving chemical changes or phase transitions the driving free energies range from a few to 100 kJ/mol. While the excess free energy associated with a nanoscale microstructure is only a few kJ/mol, this level is sufficient to alter the relative phase stability and to modify the path of kinetic reactions.

Advances in analysis

The analysis of phase stability during phase transformations has been advanced by a number of computational methods. The widely used Calphad approach (Saunders and Miodownik, 1998) is most effective in leveraging experimental data to provide a full evaluation of alloy phase stability. Moreover, the Calphad assessment provides the basis to evaluate the component mobilities that

Table 1 Comparison of the driving free energies for some phase transformation reactions.

Reaction process	Free energy	Typical value (J/mol) $T = 1000\text{ K}$	Remarks
Crystallization polymorphic transition	$\Delta H_f \Delta T / T_m$	$3 \cdot 10^3$	
Mixing/interdiffusion	$RT(X_A \ln X_A + X_B \ln X_B)$	$5 \cdot 10^3$	Ideal solution behavior
Oxidation	$\Delta G^0 = -RT \ln K$	$5 \cdot 10^4 - 5 \cdot 10^6$	ΔG^0 —formation of oxide K—equilibrium constant
Sublimation/condensation	$\Delta H_v \Delta T / T_s$	$10^4 - 10^5$	ΔH_v —sublimation enthalpy T_s —sublimation temperature
Grain growth, coarsening	$2\sigma/r$	20 for $r = 1\text{ }\mu\text{m}$ $2 \cdot 10^3$ for $r = 10\text{ nm}$	$\sigma = 1\text{ J/m}^2$
Precipitation	$RT \ln (X_s/X_0)$	10^4	$X_s/X_0 = 10$
Cold work (stored energy)	$\rho G b^2$	$10^2 - 10^3$	G—shear modulus b—Burgers vector ρ —shear modulus [☆]

can be used by programs such as Dictra or Pandat or other methods such as phase field analysis (Boettinger and Warren, 1996; Qin and Bhadeshia, 2010) to model phase transformation kinetics and microstructure evolution. For cases where there is a lack of data other approaches such as density functional theory (Argaman and Makov, 2000) can provide the missing phase stability analysis. All of these methods have provided unprecedented access to the rich variety of alloy phase stability and transformation behavior that has enabled a more effective and efficient design of alloys.

Conclusion

This chapter provides coverage of the essential features of phase transformation thermodynamics. From the initial definition of equilibrium conditions the discussion covers the thermodynamics of pure components and alloy systems. With the background on the basic thermodynamic factors involved in phase transformations the discussion focuses on the phase stability hierarchy concerning nucleation-controlled reactions, competitive phase selection and metastability. Two topics of contemporary interest in thin film systems and the early stage of phase transformations are discussed in terms of constrained equilibrium and the thermodynamics of nanoscale materials. The evolving approaches in the analysis of phase stability based upon density functional theory are highlighted as important developments.

Abstract

Incommensurately modulated crystalline phases are part of a more general family called aperiodic crystals. Their symmetry is treated within the theoretical framework of superspace groups that is a generalization of the 3D space groups that are used for conventional crystalline structures. Aperiodic structures are conveniently embedded in superspace with dimensions varying from $(3 + 1)$ to $(3 + 3)\text{D}$. They do occur in all types of material, organic and inorganic, metal and alloys, minerals and macromolecules under various pressure and temperature. Some examples of incommensurate structures are presented along with their chemical and physical properties.

Key points

- Incommensurate crystalline phases are part of a more general group of structures called *aperiodic* which do not exhibit the usual periodicity in three dimensions. They are however perfectly ordered structures as witnessed by essentially discrete diffraction pattern.
- The symmetry of incommensurate structures are described in superspace with dimensions varying from four to six.
- They exhibit interesting physical and chemical properties which can be exploited in material sciences.

Introduction

Incommensurate phases or more precisely incommensurately modulated crystalline phases are a relatively modern concept in crystallography. The concept was introduced in the 1970s following the discovery of a new class of materials which did not conform to the classical model of crystalline structures. The fingerprint of a classical crystalline structure placed in an incident beam with a adequate wavelength consists of a diffraction pattern where each diffracted beam can uniquely be associated to a three dimensional grid called reciprocal space. Thus every diffracted intensity $I(h_1, h_2, h_3)$ can unambiguously be associated to three integers h_1, h_2, h_3 , which are called the Laue indices. The diffracted intensities can thus be analyzed in terms of parallel sections of two dimensional grid points. Each grid point is characterized by two integers and associated with the corresponding diffracted intensity.

The first observations of deviations from the classical model of crystals already appeared in the literature in the 1950s. First it was observed that the spins of magnetic materials did form helical structures with a pitch independent of the structural three dimensional periodicity. Later it was observed that some alloys exhibited additional diffraction spots which did not fit with the classical three dimensional grid points. These additional spots were called satellite reflections and were associated to a structural long range order independent of the three dimensional periodicity of the structure.

An important milestone in the origin of satellite reflections appeared in 1967 and was due to Korekava and Jagodzinski based on the study of the mineral Labradorite (Korekawa and Jagodzinski, 1967). The authors reported two types of satellites related to two scale length in the diffraction patterns of Labradorite. The first type of satellites (e-satellites) were associated with a periodicity of 50 Å whereas the second type of satellites (s-satellites) were attributed to a periodicity between 1400 and 1800 Å which are linked to the iridescence (or Schiller) effect characteristic of the mineral Labradorite. It was later shown that the s-satellites correspond to large alternating domains which are also subdivided in alternating subdomains corresponding to the e-satellites. Each domain contains various specific concentrations of Ca, Na, Al, and Si atoms.

At this point, the theory of satellite reflections was considered as an interesting topic but did not immediately contributed to new developments for one clear reason. The material specialists did not have the necessary tools to handle in a unified way the resolution of structures containing both main and satellite reflections. The missing link was a theoretical development of the symmetry characteristics to describe structures presenting satellite reflections. In other words, a generalization of the notion of space groups, which is so fundamental for the resolution of classical structures, had to be developed.

The first decisive publication on the symmetry of modulated structures, i.e., structures presenting satellite reflections in their diffraction patterns, was published by de Wolff (Dewolff, 1974). The author described for the first time the concept of superspace, i.e., the symmetry tools to characterize modulated structures. The method to calculate the corresponding structure factors which are fundamental to solve the structure were also introduced in order to obtain the electron density of the structure. The resolution of the modulated structure of sodium carbonate, Na_2CO_3 , was at the origin of this new development. We shall come back to this structure at a later stage. With further contributions by Yamamoto et al. (1985), the toolbox necessary to deal with the symmetry of modulated structures was completed and the method of solving them could be definitely established. Soon many examples of incommensurately modulated structures were published including minerals, metals, organic and inorganic structures.

The concept of modulated structures was further extended a decade later when Shechtman et al. discovered quasicrystalline structures (Shechtman et al., 1984). Incommensurately modulated structures and quasicrystals are parts of a larger group of materials called aperiodic crystals. In the next sections, we shall first introduce the theoretical background leading to superspace, an extension of the symmetry of crystalline structures adapted to aperiodic crystals and incommensurately modulated structures in particular. We shall then present a few examples of incommensurate structures and show how they affect some physical properties.

Theoretical presentation of superspace for the description of aperiodic structures

In classical structure, the positions of each atom is given relatively to the origin of the unit cell which in the most general case is characterized by six parameters namely the magnitudes of the three vectors $\mathbf{a}_1$, $\mathbf{a}_2$, and $\mathbf{a}_3$ and the corresponding angles α_1 , α_2 , and α_3 . The cell parameters are obtained from X-rays, neutron or electron diffraction pattern of the crystal and it is therefore convenient to introduce the reciprocal cell parameters because diffraction phenomena are better analyzed in terms of reciprocal space.

Reciprocal cell vectors are defined according to the following scalar product, i.e., the orthogonality relation

$$\mathbf{a}_i \cdot \mathbf{a}_j^* = \delta_{ij} \quad (1)$$

with reciprocal vectors indicated by *. Here δ_{ij} is the Kronecker symbol which is 1 if $i = j$ and 0 if $i \neq j$. For classical crystals, i and j vary from 1 to 3. (Physicists usually includes a factor 2π in this relation. Crystallographers however prefer to omit this factor.)

Diffraction patterns of classical structures can be analyzed in terms of a three dimensional grid determined by the three reciprocal vectors. Each grid or lattice point is specified by the three integers h_1 , h_2 , and h_3 and the measured intensity of each diffracted beam can be uniquely associated to the reciprocal lattice vector.

$$\mathbf{h} = h_1 \mathbf{a}_1^* + h_2 \mathbf{a}_2^* + h_3 \mathbf{a}_3^* \quad (2)$$

The analysis of the diffraction pattern of the modulated structure $\gamma\text{-Na}_2\text{CO}_3$ illustrated in Fig. 1 shows the reconstructed layer with indices $h_1 2h_3$ of the diffraction pattern. It is immediately clear that we do not observe a regular two dimensional disposition of grid points. The satellites reflections are all aligned along the vector $\mathbf{q}$ called the modulation vector. They are also equidistant. Each satellite row is centered around a lattice point located at the intersection of a grid (thin black lines) subtended by the reciprocal lattice vectors $\mathbf{a}_1^*$ and $\mathbf{a}_3^*$ located on the thick black lines. Based on the three vectors $\mathbf{a}_1^*$ and $\mathbf{a}_3^*$ and $\mathbf{q}$, every reflection in the layer I can be indexed with three integers.

$$\mathbf{l} = h_1 \mathbf{a}_1^* + h_3 \mathbf{a}_3^* + m \mathbf{q} \quad (3)$$

When $m = 0$, $\mathbf{l}$ represents a main reflection whereas for $m \neq 0$, $\mathbf{l}$ represents a satellite reflection. Thus the complete diffraction pattern of $\gamma\text{-Na}_2\text{CO}_3$ can be indexed by four integers in the form.

$$\mathbf{H} = h_1 \mathbf{a}_1^* + h_2 \mathbf{a}_2^* + h_3 \mathbf{a}_3^* + m \mathbf{q} \quad (4)$$

The modulation vector $\mathbf{q}$ can be expressed in terms of three reciprocal lattice vectors $\mathbf{a}_i^*$ with coefficients α_i .

$$\mathbf{q} = \alpha_1 \mathbf{a}_1^* + \alpha_2 \mathbf{a}_2^* + \alpha_3 \mathbf{a}_3^* \quad (5)$$

The coefficients can be obtained experimentally. When at least one of them is irrational, the modulated structure is incommensurately modulated. This is often the case when the coefficients are temperature or pressure or composition dependent.

The increase of the number of reciprocal space vectors to fully characterize the diffraction pattern of modulated crystals requires an embedding in the so called superspace. In the particular case of $\gamma\text{-Na}_2\text{CO}_3$, we shall introduce the four new reciprocal basis vectors $\mathbf{a}_{S1}^*$, $\dots$, $\mathbf{a}_{S4}^*$ and express them in terms of external and internal components along the scheme given in Fig. 2. Once the reciprocal vectors are defined in superspace, we can use the orthogonality relations to find the corresponding direct space embedding for the description of the crystal structure,

Fig. 1 The reconstructed $h_1 2 h_3$ reciprocal lattice plane from an experimental single crystal diffraction pattern of $\gamma - \text{Na}_2\text{CO}_3$.

Fig. 2 Embedding of the 3D reciprocal space into superspace of dimension $3 + 1$. The reciprocal space vector $\mathbf{a}_{S4}^*$ has an *external* component $\mathbf{q}$ and an *internal* component $\mathbf{e}_4^*$ normal to $\mathbf{a}_1^*$, $\mathbf{a}_2^*$, and $\mathbf{a}_3^*$.

$$\left. \begin{aligned} \mathbf{a}_{S1}^* &= (\mathbf{a}_1^*, 0) \\ \mathbf{a}_{S2}^* &= (\mathbf{a}_2^*, 0) \\ \mathbf{a}_{S3}^* &= (\mathbf{a}_3^*, 0) \\ \mathbf{a}_{S4}^* &= (\mathbf{q}, 1) \end{aligned} \right\} \rightarrow \mathbf{a}_{Si}^* \cdot \mathbf{a}_{Sj}^* = \delta_{ij} \rightarrow \begin{cases} \mathbf{a}_{S1} = (\mathbf{a}_1, -\mathbf{q} \cdot \mathbf{a}_1) \\ \mathbf{a}_{S2} = (\mathbf{a}_2, -\mathbf{q} \cdot \mathbf{a}_2) \\ \mathbf{a}_{S3} = (\mathbf{a}_3, -\mathbf{q} \cdot \mathbf{a}_3) \\ \mathbf{a}_{S4} = (0, 1) \end{cases} \quad (6)$$

In order to analyze the modulated structure, it is convenient to describe it in the superspace embedding as illustrated in Fig. 3. In this example, the modulation of the structure is a simple sinusoidal displacement with wavelength λ in the $\mathbf{a}_2$ direction. In other words $\mathbf{q} = \alpha_2 \mathbf{a}_2$. The wavelength satisfies the relation $\lambda = 1 / \|\mathbf{q}\|$ and in general it is incommensurate relative to at least one of the cell constants $\mathbf{a}_i$. The structure can be analyzed in terms of $(\mathbf{a}_{Si}, \mathbf{a}_{S4})$ sections with $i = 1$ to 3. The directions $\mathbf{a}_i$ and $\mathbf{a}_{Si}$ are different if the scalar products $\mathbf{q} \cdot \mathbf{a}_i \neq 0$. We observe that the horizontal line “real crystal” or any other parallel line in Fig. 3(B) does reproduce the displacements of the atom with coordinates x_2 around its average position $\bar{x}_2$ indicated in Fig. 3(A). It is now straight forward to imagine the corresponding $(\mathbf{a}_{S1}, \mathbf{a}_{S4})$ section corresponding to Fig. 3(B). The scalar product $\mathbf{q} \cdot \mathbf{a}_1 = 0$ and consequently the shape of the periodic motif would be rectangular. With no modulation component in the $(\mathbf{a}_{S1}, \mathbf{a}_{S4})$ section, the shape of the modulation would be a straight line $x_1 = \bar{x}_1$.

Fig. 3 Embedding of a modulated structure in 3 + 1 dimensions. The sinusoidal modulation along $\mathbf{a}_2$ given in (A) is extended in superspace according to the model indicated in (B). See the text for further information.

Fig. 4 Two examples of modulation functions. (A) Step function characterizing two possible locations of the same atom in the crystal structure. (B) Example of various stacking sequences for closed packed layers with three possible stacking positions A, B, or C.

For the description of modulated structures, we see from Fig. 3(B) that the x_4 component is ill suited for analyzing the relations between atomic positions. Therefore the variable t , which satisfies the relation

$$t = x_4 - \mathbf{q} \cdot \mathbf{r}, \quad (7)$$

is preferred for practical purposes. Here $\mathbf{r}$ defines the position of an atom in the unit cell defined by $\mathbf{a}_1$, $\mathbf{a}_2$, and $\mathbf{a}_3$.

Since the introduction of the superspace, a large array of possible modulation functions have been successfully used. The most general modulation function can be approximated by a series of harmonic terms. Other possibilities like crenel or step functions as well as sawtooth and other functions have been successfully applied (Petříček et al., 2014) depending on the nature of the modulation function. Fig. 4 illustrates two possible types of modulated function.

With the example of γ - Na_2CO_3 the superspace model was derived in (3 + 1)D. Since the development of superspace many more examples were discovered requiring an extension of the superspace to higher dimensions. Modulated structure models can possibly exist up to (3 + 3)D. We recall that the first number in the parenthesis is the space (or external) dimension of the structure and the second number is the dimension of the internal space. The rank of the structure is the sum of both numbers. Icosahedral quasicrystals (QC) for example, are described in (3 + 3)D whereas decagonal QC are described in (3 + 2)D. Most of the incommensurately modulated phases are described in (3 + 1)D but there are a few examples of (3 + 2)D including composite structures. The modulated structure of Lazurite and the modulated structure presented in Section “Structure evolution of the organic perovskite $\text{CH}_3\text{NH}_3\text{PbI}_3$ by thermal cycling around the phase transitions” is a rare example of non-QC structures described in (3 + 3)D.

We have seen above that the reciprocal space of aperiodic crystal structures can be analyzed in terms of external (also called physical or parallel) and internal (also called perpendicular) space dimensions. Fig. 5, inspired from the publication of Yamamoto (Yamamoto, 1996), illustrates the principal differences between the three families of aperiodic crystal structures. For modulated crystals, the prominent main reflections are all located along R_E . In composites, two (or more) series of prominent reflections are aligned along lines crossing the origin whereas for QC, the prominent reflections do not exhibit any periodicity.

The structural resolution of aperiodic crystals and in particular modulated structures has made enormous progress in the past decades and excellent open software is readily available. The electron density of a (3 + 1)D modulated structure can be obtained from the Fourier transform of the structure factor which is given as

Fig. 5 Characteristics of aperiodic crystal families according to their reciprocal space embeddings. R_E and R_I indicate the external and internal space components.

$$F(\mathbf{H}) = \sum_j f_j(\mathbf{H}) \exp(2\pi i \mathbf{H} \cdot \mathbf{r}_j) \times \int_0^1 dt p_j(t) \exp\{2\pi i (\mathbf{H} \cdot \mathbf{u}_j(t) + h_4 t)\}. \quad (8)$$

The first line of the equation is very similar to the structure factor of a classical 3D crystal with the reciprocal vector $\mathbf{H}$ defined in (4). The term $\mathbf{u}_j$ in the second line characterizes the displacement of the atom j along t defined in (7) from the average position $\mathbf{r}_j$. Here $h_4 = m$ defined in (4). The population parameter $p_j(t)$ for example, can express the presence or absence of the specific atom j in some portion of the structure or an atomic position substituted by another one.

The determination of the displacement function $\mathbf{u}_j$ is the subject of the structure resolution algorithms treated in another chapter of the present encyclopedia.

The crystallographic model of a modulated structure obtained by exploiting the diffraction measurements can be analyzed in terms of two-dimensional sections of the type $(\mathbf{a}_{Si}, \mathbf{a}_{S4})$ with i varying from 1 to 3. In general, many sections are needed in order to completely characterize the structure. The nature of the modulations is usually presented in forms of t -plots which give some information about all possible conformations occurring in the crystal space. It can be interatomic or contact distances and angles. It can also represent occupational or substitutional parameters or some other meaningful crystal chemical parameters. Due to the aperiodic nature of the crystal structure, only selected portions of the crystal structure can be illustrated. This differs from the classical crystal structure where the unit cell content suffices to fully represent the structure.

We cannot terminate this section without discussing the important topic of symmetry. The sine qua non condition to determine and refine a classical crystal structure is to know its space group. There are 230 of them in 3D. It is due to the work of de Wolff, Janner and Janssen (Janssen et al., 2018) that the field of aperiodic crystals could evolve by deriving the superspace groups up to rank 6, i.e., up to $(3 + 3)\text{D}$. Owing to the very large number of possible cases, the list of superspace groups can be directly accessed from the web (Stokes et al., 2011). There are 775 superspace groups in $(3 + 1)\text{D}$, 3'338 in $(3 + 2)\text{D}$ and 12'584 in $(3 + 3)\text{D}$!

The theoretical derivation and the development of superspace group symmetry is beyond the scope of this chapter. The interested user may consult the references cited in (Janssen et al., 2018) for further reading.

In the next sections, we shall explore a selection of incommensurate structures which have been solved experimentally and relate them to some specific physical and chemical properties.

The habit of Calaverite ($\text{Au}_{1-x}\text{Ag}_x\text{Te}_2$ with $x < 0.15$) or the macroscopic manifestation of incommensurate phases

One of the most fundamental laws concerning the habit or shape of (macroscopic) crystals is Haüy's law stating that every crystal face can be uniquely characterized by three integer indices also called Miller indices. This law was so anchored among scientists since the beginning of the 18 century that none would dare to question the general validity of the law although some experimental data were at hand to disprove it. The discovery of X-rays diffraction in 1912 revealed the intimate relation between the Laue indices characterizing the diffracted beam and the Miller indices of the crystal faces.

The difficulties to index the crystalline faces of Calaverite were already mentioned well before the discovery of X-ray diffraction. The most important study on indexing Calaverite crystals appeared in 1931 by Goldschmid, Palache and Peacock (see Dam et al. (1985) and references cited therein). 105 specimens from various worldwide origins including 92 crystal forms lead to the conclusion that the law of rational indices was not of general validity! The authors were obviously right as it was later confirmed but the publication did not lead immediately to further developments. Only 52 years later, Amelinckx and coworkers found by high resolution electron microscopy (HREM) that Calaverite exhibited an incommensurately modulated structure with the modulation vector $\mathbf{q} = (\alpha_1, 0, \alpha_3)$. This discovery led Dam, Janner and Donnay to use the 1931 data to propose a new indexation of the faces

with integer indices corresponding to the rank of the structure, i.e., the minimal number of integer coefficients necessary to fully index the diffraction pattern. The rank of Calaverite being four, every reciprocal vector $\mathbf{H}$ associated with each diffracted beam must satisfy the following relation.

$$\mathbf{H} = h_1 \mathbf{a}_1^* + h_2 \mathbf{a}_2^* + h_3 \mathbf{a}_3^* + m \mathbf{q} \quad (9)$$

with

$$\mathbf{q} = \alpha_1 \mathbf{a}_1^* + 0 \mathbf{a}_2^* + \alpha_3 \mathbf{a}_3^*. \quad (10)$$

This approach was very successful and led to the new characterization of the faces illustrated in Fig. 6. It was first realized that the crystals of Calaverite were twins and moreover, the components α_1 and α_3 of the modulation vector could be deduced from the optical goniometer measurements with a precision close to the values obtained by modern diffractometer measurements. The ultimate confirmation of the incommensurate nature appeared 3 years later when Schutte and de Boer (ref. cited in Dam et al. (1985)) published the complete resolution of the structure in the superspace formalism.

The study shows that the structure of the incommensurate Calaverite consists of parallel edge sharing layers of Te octahedra centered with (Au, Ag). The layers are stacked in the third dimension. The origin of the incommensurate modulation is due to an ordered substitution of Ag atoms which is independent of the lattice parameters.

What can be said on the stability of the crystal faces of Calaverite? Fig. 6 shows that most of the indices of the faces correspond to satellite reflections, i.e., $m \neq 0$. Only three of them correspond to main reflections ($m = 0$). In other words, faces corresponding to main or satellite reflections do not distinguish themselves as far as their stability is concerned. Moreover, the example of the Calaverite faces is not an exception and many other examples are known (see Dam et al. (1985)).

Sodium carbonate Na_2CO_3

Sodium carbonate is a very interesting example illustrating the interplay between commensurate and incommensurate phases occurring at different temperatures. It is also interesting because of its role in establishing a new paradigm in crystallography, namely the concept of superspace to characterize the symmetry of incommensurate structures or more generally aperiodic crystal structures.

Let us first describe the general features the Na_2CO_3 structure (Brouns et al., 1964; Arakcheeva and Chapuis, 2005) illustrated in Fig. 7. The structure can be interpreted in terms of a series of identical layers staked in the third dimension. Each layer consists of graphite-like layers with C and Na atoms. Each C atom is linked to three Na atoms and similarly, each Na atom is linked to three C atoms. The three O atoms of the carbonate group form nearly equilateral triangles around C atoms. We shall not deal further with the O atoms as their role in the phase transition mechanisms are secondary. In other words, we shall essentially study the role of the second coordination spheres around C.

Fig. 6 The indexation of the twinned incommensurate structure of Calaverite in $(3 + 1)\text{D}$. Colors distinguish the twin components. The illustration is based on the figure published in (Dam et al., 1985).

Fig. 7 A portion of the room temperature form of γ - Na_2CO_3 interpreted as a layer structure. Small and large spheres are C respectively Na atoms. O atoms are omitted for clarity.

In sodium carbonate, we can distinguish two types of sodium atoms, namely Na3 on one side and Na1 and Na2 on the other side. Na3 is part of the graphite-like layers whereas Na1 and Na2 are located halfway between the layers in alternating mode. From the chemical point of view, it turns out that Na3 behaves differently than Na1 and Na2. Thus, in this structure they can be interpreted as different chemical species.

Table 1 illustrates the sequence of second order phase transitions occurring between 754 and 170 K. The transition from the hexagonal α phase to the monoclinic β phase occurs following a shear deformation parallel to the graphite-like layer planes. Below 605 K, two incommensurate phases are observed resulting in the commensurate lock-in phase δ below 170 K.

We shall attempt to understand the nature of the incommensurate phase γ by analyzing various planar sections containing the C and Na atoms. The hexagonal high temperature phase α exhibits three mirror planes containing the hexagonal axis which are indicated by m_M and m_V in the inset of Fig. 8. The shear transformation occurring at the α to β transition results in the disappearance of two of the three mirror planes. Only mirror m_M remains. The right part of Fig. 8 represents the planar sections of the γ phase in the unique m_M plane which remains after the transition but also the planar section of the m_V (V for virtual) which only exists in the high temperature phase. The incommensurate γ phase consists of clusters which are similar to other phase portions at various temperatures. We can distinguish two main features, namely the regular section m_M indicated in Fig. 8 and the irregular section m_V . Only C-Na contact distances are indicated. Whereas the m_M section of phase γ is similar to the corresponding section of phase β , this is not the case of the other section m_V . Here the content of the m_V section of the incommensurate structure γ consists of different clusters which can be found at different temperatures but within the range of existence of phase β . Apparently, the regular structural motif observed in the m_M section cannot be realized in the m_V section. However, some parts of the motif can be accommodated locally in the form of clusters. This is at the origin of the incommensurate nature of the phase γ .

At this point, one may ask the question about the driving force behind the sequence of phase transitions occurring at different temperatures. It appears that the C atoms attempt to increase the number of C-Na contact distances by decreasing temperature. This is reflected in the coordination number of C-Na contacts distances less than 3.1 Å indicated in the above table. This number increases constantly for each phase starting from three in phase α to reach the number of seven in the lock-in phase δ .

The structural analysis of the incommensurate phases and the sequence of phase transitions occurring in sodium carbonate reveals two important characteristics which often occur in incommensurate structures. We observe first that two different types of Na atoms exists namely the ones (Na3) which are part of the graphite like layer structure. They behave in different ways if we compare their distances and geometries to the nearest or next nearest neighbors. On the other hand Na1 and Na2 are located between the graphite-like layers and play a different role during the phase transition mechanisms. This behavior is very well reflected in the Na-O distances. In the γ phase, the Na1-O and Na2-O distances vary from 2.3 to 2.4 Å whereas the Na3-O distances show a much larger spread varying between 2.5 and 2.9 Å. Such a structural differentiation between atoms of the same chemical species is not seldom in incommensurate structures. The host-guest type of high pressure BaIV structure (Arakcheeva et al., 2017) clearly distinguishes the guest Ba atoms located in the channels formed by the framework of the host Ba atoms. In this case, we are even dealing with a self host-guest structure.

Table 1 Phases and transition temperatures of Na_2CO_3 .

α	754 K	β	605 K	γ'	530 K	γ	170 K	δ
hexag. CN: 3		monocl. 4		monocl. incom. 5		monocl. incom. 6–7		monocl. lockin 7

Fig. 8 Analysis of the incommensurate phase γ in terms of different planar sections. The three planar sections correspond to the three mirror planes occurring in the hexagonal phase α as indicated in the inset. During the shear transformation only one mirror plane remains, m_M and the two others m_v disappear. Only contact distances smaller than 3.1 Å are represented. O atoms are omitted.

Another important aspect of incommensurate structures concerns the role not only of first nearest neighbors but also of the second nearest neighbors in the phase transition mechanisms (Arakcheeva et al., 2005). The example of Na_2CO_3 is characteristic but not unique. We have stressed above the important role of the second nearest neighbors of C atoms to drive the phase transition mechanism. Apparently the nearest neighbors of the C atoms, i.e., the O atoms, only play a secondary role in the driving force of the transition mechanism.

The luminescence of Europium containing scheelites

In this section we shall illustrate how the resolution of the incommensurate structures of a family of Europium containing scheelites did contribute to the understanding of their luminescent properties. Scheelite related compounds (SRC) with the general formula $\text{M}_n(\text{XO}_4)_m$ where M and X cover a large spectrum of elements are very stable and their preparation by solid state reactions are easy so that scheelites are found in many industrial applications including fuel cells and photocatalysts. In particular, Eu^{3+} -containing compounds exhibit interesting white-light-emitting diode properties. The study of a series of scheelites with the composition $\text{Na}_x\text{Eu}_{(2-x)/3}^{3+}\text{MoO}_4$ ($0 \leq x \leq 0.5$) gives interesting insights into the important role of incommensurate structures in determining some physical properties of solids (Arakcheeva et al., 2012).

The general feature of the Eu containing scheelites is illustrated in Fig. 9. The unit cell is composed of two cubic face centered unit cells stacked along c. The positions of the Eu, Na atoms alternates with the MoO_4 tetrahedra.

The luminescent characteristics of a series of samples with x varying between 0 and 0.5 have been measured in order to correlate them with their structural properties. The large majority of the structures are incommensurately modulated and their structures could be solved from powder diffraction data. Due to the incommensurability of the structures only finite portions of them can be represented. Fig. 10 represents portions of the cationic part of the structures projected along c.

For each specific Na/Eu ratio we observe specific incommensurate structures, the characteristics of which can all be deduced from a single superspace group. The corresponding coefficients α and β of the modulation vectors $\mathbf{q} = \alpha\mathbf{a}^* + \beta\mathbf{b}^*$ vary by only a few percents depending on the composition. As a consequence of the modulation vector, the periodicity along c remains and the propagation of the modulation is confined to the (a,b) plane. The direction of $\mathbf{q}$ is indicated in Fig. 10. In all the structures, except for the Eu/Na ratio of 1, we observe parallel lines of extended domains normal to $\mathbf{q}$ representing either Eu (dark blue) or Na (light blue) domains but also vacancies (white stars).

The incommensurate structures exhibit an outstanding feature namely the presence of Eu dimers or clusters which play an important role in relation to the luminescent characteristics of these materials. The Eu-clusters are represented in the top right of Fig. 10 and form separate entities (surrounded by yellow ellipses in the figure) which are well distinguishable. Their number are specific for each chemical composition but are not related to the Eu/Na ratio.

Fig. 9 Two representations of the of Na, Eu scheelite with MoO_4 tetrahedra. In the incommensurate structures, the yellow spheres show a well ordered distribution of the Na and Eu atoms and also their vacancies.

Fig. 10 Portions of the ab projections of the cationic part of $\text{Na}_x\text{Eu}_{(2-x)/3}^{3+}\text{MoO}_4$. The unit cells of the structures based on the main reflections only are given in red. Eu atoms (dark blue) Na atoms (light blue) and vacancies (white stars) form different aggregates depending on the composition. One of them, the Eu dimer is represented on the top right. Gray atoms indicate disorder between Eu and Na atoms.

It turns out that a linear relation can be found between the percentage of Eu-clusters relative to the total number of Eu atoms. Fig. 11 illustrates some luminescent characteristics as function of the Eu-cluster percentage. Different characteristic measurements are represented, namely, the quantum yield, Q_L^{Eu} , obtained by ligand excitation at 273 K, the intrinsic quantum yield of Eu^{3+} , $Q_{\text{Eu}}^{\text{Eu}}(\text{meas})$, and the observed lifetimes τ_{obs} at 293 and 77 K as function of the relative amount of Eu clusters, $N_{\text{Eu-cl}}/N_{\text{Eu-total}}$ in $\text{Na}_x\text{Eu}_{(2-x)/3}^{3+}\text{MoO}_4$.

An interesting question arises concerning the count of the relative number of Eu-clusters in an aperiodic structure. The distribution of the clusters represented in Fig. 10 rather show a random distribution if we consider that only portions of aperiodic structure are represented. For this purpose we can take advantage of the t -plots mentioned at the end of Section "Theoretical presentation of superspace for the description of aperiodic structures." The aim is to look at the domain of existence of Eu-Eu contact distances where each Eu has only one neighbor within a maximal specified distance. The extension of the domain in the corresponding t -plot yields the percentage of the Eu-clusters relative to the total amount of Eu present in the structure.

The study shows the important role played by incommensurate structures in revealing some structure-property relations. This is even more important regarding the fact that the satellite reflections are very weak in the case of $\text{Na}_x\text{Eu}_{(2-x)/3}^{3+}\text{MoO}_4$ and therefore can easily be overseen if the powder diffractograms lack sufficient resolution. This is why many previous studies on the origin of the luminescence of Eu-scheelites failed by considering only periodic approximations of the crystal structures.

Fig. 11 Different luminescence characteristics namely the quantum yield, Q_L^{Eu} , obtained by ligand excitation at 273 K, the intrinsic quantum yield of Eu^{3+} , $Q_{Eu}^{Eu}(\text{meas})$, and the observed lifetimes τ_{obs} at 293 and 77 K are represented in function of the relative amount of Eu clusters, $N_{Eu-cl}/N_{Eu-total}$ in $Na_xEu_{(2-x)/3}^{3+}MoO_4$.

The superspace formalism, which we used here to discover the linearity between luminescent properties and the relative content of Eu-clusters, exhibits another interesting property. The superspace formalism can be used as a predictive tool for the discovery of new physical properties in material science. In particular, it could be used to optimize the luminescent properties of some extended series of SRC by maximizing the number of clusters.

Structure evolution of the organic perovskite $CH_3NH_3PbI_3$ by thermal cycling around the phase transitions

Methyl ammonium lead iodide ($MAPbI_3$) is a very efficient light absorbing photovoltaic material with a broad spectrum of opto-electronic properties. Its properties have found applications in gas sensor, photodetectors, light-emitting diodes and solar cells in particular (Glushkova et al., 2019). Currently, $MAPbI_3$ based solar cells have reached the impressive level of 22% efficiency!

The physical properties strongly depend on the preparation methods and storage conditions, i.e., temperature and humidity. In addition, the crystal structure is subject to phase transitions which affect the electronic and photonic band structure, i.e. the transport properties. They are essentially two phase transitions occurring at low temperature (160 K) and high temperature (330 K).

In the temperature range from 100 to 352 K, we observe essentially two types of structural modifications occurring during the phase transitions. The first concerns the orientations of the C—N bonds which are linked to the inorganic framework by H-bonds between the N and I atoms. The room temperature pristine form of the organic perovskite $CH_3NH_3PbI_3$, methylammonium lead iodide, is tetragonal, space group $I422$ and is illustrated in Fig. 12. Already at room temperature, a superposition of four different disordered C—N bonds can be observed. The second type of changes occurring during the transition mechanisms concerns a slight rotation of the octahedra about the tetragonal axis. Consequently each corner sharing octahedra in the plane rotates about the same amount but in the opposite direction. The two types of structural modifications are not independent and the H bonded links tend to adopt the best possible orientation depending on the closest contact distances with the iodine atoms.

Under standard operating conditions, solar cells with encapsulated $MAPbI_3$ layers can reach over 360 K crossing thus the transition temperature twice each day. A deep understanding of the repeated phase transition mechanisms is thus necessary in order to optimize the working conditions of the solar cells. The following study shows the effect on the structural modifications of the thermal cycling around the high temperature phase transition. It appears that $MAPbI_3$ does not return to the initial structural state but reaches an equilibrium structure which is specific for the phase transition temperature. The cycling around the high temperature

Fig. 12 The pristine structure of the organic perovskite $\text{CH}_3\text{-NH}_3\text{PbI}_3$, methylammonium lead iodide. The tetragonal form consists of a 3D grid of PbI_3 octahedra sharing common vertices with their nearest neighbors. The methylammonium (MA) groups represented here without hydrogens are located in the cavities formed by the framework of octahedra. In the tetragonal form, each MA site is disordered and consists of a superposition of four different C—N bonds orientations.

Fig. 13 Evolution of the characteristics of two satellite reflections in the high temperature range of the phase transition depending on the number of cycling. The initial tetragonal structure transforms to an incommensurately modulated tetragonal phase which reaches equilibrium after a limited number of transitions.

phase transition gives rise to an incommensurately modulated phase reaching stability already after a few number of successive transitions as indicated in Fig. 13. Both left and right figures consist of two parts, α and γ components of the characteristic satellite reflection (left ordinate) and the intensities of the satellite (right ordinate). Up and down refers to the increase respectively decrease of the temperature around the phase transition. On the first cycling process, α remains rational by increasing temperature (red color) until the phase transition occurs. Above 340 K the value reaches 0. For γ on the other hand, the value decreases and becomes incommensurate reaching 0 above 340 K. By decreasing temperature (green color) both α and γ components remain incommensurate till the end of the first cycle. The sixth cycle shows that the incommensurate phase is well settled and no more variation of the α and γ components can be observed.

In order to see the effect of the modulation on the structure, a 30 nm square portion of the non-periodic structure is illustrated in Fig. 14 for two different temperatures. For clarity, the organic part of the structures has been omitted. Both figures show domains with the same periodicity. However, due to different intensities of the satellite reflections, the temperature dependent nano domains exhibit different amplitudes of the rotations of the lead iodide octahedra. In the temperature range between 310 and 350 K, we

The (3+3)D superspace group is $P4/mmm(\alpha_1, \alpha_1, 0)0s0s(-\alpha_1, \alpha_1, 0)0s00(0, 0, \gamma_2)00ss$ (No. 123.3.174.104) with unit cell parameters: $a = 6.309(3)$, $c = 6.311(3)$ Å and modulation vectors: $\mathbf{q}_1 = 0.4861\mathbf{a}^* + 0.4861\mathbf{b}^*$; $\mathbf{q}_2 = -0.4861\mathbf{a}^* + 0.4861\mathbf{b}^*$ and $\mathbf{q}_3 = 0.4718\mathbf{c}^*$.

Fig. 14 Two portions of the incommensurate MAPbI_3 structure at different temperatures. We observe the formation of nano domains with the same periodicity given by the modulation vector $\mathbf{q}$. The domains are essentially due to various tilt angles of lead iodide octahedra relative to the tetragonal unit cell vectors.

observe also a small linear temperature dependency of the lattice parameters which changes by less than 0.01 Å both in increasing and decreasing temperatures.

The interaction between the inorganic and organic parts of the structure is the principal cause of the phase transitions. The stability of the structure might be improved by some cationic substitution and indirectly influence the electronic properties of the material. Other approaches have been proposed, e.g., by introducing some inert gas into the framework of the structure leaving ample possibilities to improve the stability of the structure.

Conclusion

Only very limited aspects of incommensurately modulated structures could be illustrated in this presentation. Modulated structures are not rare, on the contrary they appear in all possible categories of materials from small molecules to macromolecules, in metals and alloys under high pressure and often in minerals. Before the discovery of aperiodic crystals and the introduction of the very powerful superspace tools, many structures were published as conventional 3D structures but often with “disordered” character. Some of them were later successfully reinterpreted in terms of well ordered incommensurately modulated structures. Many examples of scheelite structures as described in Section “The luminescence of Europium containing scheelites” fit into this scheme.

We have to stress at this point that incommensurate structures cannot be classified as disordered structures. On the contrary, they are very well ordered structures as indicated by the presence of discrete satellite reflections. This order goes beyond the 3D unit cell periodicity and mostly appears in terms of nano domains as exemplified in the case of MAPbI_3 described in Section “Structure evolution of the organic perovskite $\text{CH}_3\text{NH}_3\text{PbI}_3$ by thermal cycling around the phase transitions.” It is however not excluded that the appearance of satellite reflections might be accompanied with the presence of diffuse scattering in the diffraction patterns, especially in cases of phase transitions where some dynamical rearrangements occur in the formation of nano domains depending on the temperature or pressure variation.

There is another interesting aspect concerning the utility of the superspace group concept. Initially the superspace was developed to characterize the symmetry of incommensurate structures. This concept however is a very powerful tool to predict and explore new structures with specific physical properties as described in reference (Arakcheeva and Chapuis, 2008). It is also very useful to describe families of compounds containing both commensurate (3D) and incommensurate (3 + n)D members. The interesting feature here is that only one single superspace group is sufficient to describe the complete series of members of the family characterized by a large range of elements, chemical composition and topology.

Abstract

As early as 1867, two years after the introduction of the concept of entropy by Clausius, Maxwell showed that the limitations imposed by the second law of thermodynamics depend on the information that one possesses about the state of a physical system. A “very observant and neat-fingered being,” later on named *Maxwell demon* by Kelvin, could arrange the molecules of a gas and induce a temperature or pressure gradient without performing work, in apparent contradiction to the second law. One century later, Landauer claimed that “information is physical,” and showed that certain processes involving information, like overwriting a memory, need work to be completed and are unavoidably accompanied by heat dissipation. Thermodynamics of information analyzes this bidirectional influence between thermodynamics and information processing. The seminal ideas that Landauer and Bennett devised in the 1970s have been recently reformulated in a more precise and general way by realizing that informational states are out of equilibrium and applying new tools from non-equilibrium statistical mechanics.

Introduction

The connection between information and thermodynamics was first revealed by the celebrated Maxwell demon, a gedanken experiment that Maxwell devised shortly after his discovery of the distribution of velocities in an equilibrium gas. The velocity distribution revealed that temperature is proportional to the average kinetic energy of molecules, but their speeds cover a wide range of values. Maxwell considered two gases, a hot one *A* and a cold one *B*, confined respectively in two containers separated by a wall or diaphragm. Then he imagined an external agent or demon as “a finite being who knows the paths and velocities of all the molecules by simple inspection but who can do no work except open and close a hole in the diaphragm by means of a slide without mass.” In a letter to his friend Tait, dated December 11th 1867, Maxwell describes for the first time the operation of the demon:

Let him first observe the molecules in *A* and when he sees one coming the square of whose velocity is less than the mean square velocity of the molecules in *B*, let him open the hole and let it go into *B*. Next, let him watch for a molecule of *B*, the square of whose velocity is greater than the mean square velocity in *A*, and when it comes to the hole let him draw the slide and let it go into *A*, keeping the slide shut for all other molecules. Then the number of molecules in *A* and *B* are the same as at first, but the energy in *A* is increased and that in *B* diminished, that is, the hot system has got hotter and the cold colder and yet no work has been done, only the intelligence of a very observant and neat-fingered being has been employed.

Maxwell published the idea, four years after the letter to Tait, in a section of his book, *Theory of Heat* (1871). The section is entitled “Limitation of the second law of thermodynamics.” Later on, Lord Kelvin coined the name Maxwell’s demon for this “neat-fingered being,” and it has been subject of constant controversy until nowadays (Leff and Rex, 1990). The original Maxwell demon opened at least two important lines of research.

The first one is based on a simpler version of the Maxwell demon, also known as pressure demon. In this variant, the demon opens the door only when a particle from the left half of the container is moving to the right half, that is, he allows particles to cross only from left to right. By doing so, the demon accumulates particles in the rightmost half of the container, increasing its density and inducing a pressure difference that can be subsequently used to obtain work. Notice that, in principle, a simple valve, like the one depicted in Fig. 1, could do the same job as the demon. However, this naive idea does not work because the valve is subjected to thermal fluctuations that randomly open the gate and allow particles to cross in the “wrong” direction. In fact, there is a fundamental impossibility of rectifying thermal fluctuations due to the reversibility of microscopic dynamics (Ehrich et al., 2019). The celebrated Smoluchowsky-Feynman ratchet (Feynman et al., 1966; Smoluchowski, 1912) is another example of autonomous Maxwell demon, which cannot rectify thermal fluctuations from a single bath. Feynman went further and assumed

Fig. 1 The autonomous pressure Maxwell demon.

that the ratchet is immersed in a fluid at a temperature lower than the source of the fluctuations and proved that then the ratchet is indeed able to rectify and perform work. Nevertheless, the second law is not defeated since now the system is in contact with two thermal baths at different temperatures and the whole setup acts as a thermal machine. Feynman showed that the efficiency of such a motor cannot be higher than the Carnot efficiency, in agreement with the second law.¹ This approach can be applied to generic classical systems in contact with thermostats and/or chemostats. The idea has yielded a fruitful line of research on Brownian motors (Reimann, 2002), systems that exhibit systematic motion or perform work using gradients of temperature and/or chemical potential, with applications in biology and nanotechnology (Bustamante et al., 2001; Feng et al., 2021). The role of information in Brownian motors is not completely clear, although we introduce in Section “Information flows” the concept of information flows in autonomous systems, which allows one to analyze some of these machines as an exchange between information and entropy (Allahverdyan et al., 2009; Horowitz and Esposito, 2014).

The second line of research directly concerns the use of information by the original Maxwell’s demon (Leff and Rex, 1990; Parrondo et al., 2015; Sagawa, 2012a,b). Two questions immediately arise from the fact that the demon can beat the second law using information. First, can we derive a quantitative relationship between the entropy decrease and the information that the demon possesses? Or, in other words, how the acquisition of information modifies the second law? Second, can we restore the validity of the second law by finding an entropy cost associated to the acquisition and/or manipulation of information by the demon? Thermodynamics of information addresses these two questions. However, it is convenient to analyze them separately. We discuss the first question in Section “Second law for feedback processes” and the second one in Section “Restoring the second law.”

In 1929, Szilárd introduced a simplified version of the Maxwell demon known as the Szilárd engine (Szilárd, 1929), which is more suitable for the resolution of these issues. It consists of a single-molecule gas at temperature T in a box of volume V . This means that the molecule thermalizes at temperature T in any collision with the wall, i.e., the outgoing velocity is a random variable distributed according to the corresponding equilibrium distribution. An external agent or demon performs the cyclic operations sketched in Fig. 2. First, he inserts a piston at the middle point of the container and measures in which of the two halves the particles lies. With this information, the demon can realize a reversible isothermal expansion by opposing a force to the pressure P exerted by the single-molecule gas. In the expansion, the demon extracts a work

$$W_{\text{extract}} = \int_{V/2}^V P dV' = \int_{V/2}^V \frac{kT}{V'} dV' = kT \ln 2 \quad (1)$$

where we have used the equation of ideal gases, $PV' = NkT$, with $N = 1$, and k is the Boltzmann constant. Finally, the piston is removed and the cycle is completed. In principle, the insertion and removal of the piston can be performed without any energy expenditure.² Hence, the Szilárd engine is able to extract energy from a single thermal bath in a cycle, in apparent contradiction to the second law.

Fig. 2 The Szilárd engine.

¹Feynman also proved that the thermal ratchet can reach Carnot efficiency in the limit of zero power. However, this result has been subject to some criticism: an autonomous thermal machine can reach Carnot efficiency only in the case of tight coupling between heat flow and mechanical work, something that it is not possible to reach in the original setup by Smoluchowsky and Feynman (Parrondo and Español, 1996).

²This is not true for a quantum particle at low temperature because, due the Heisenberg uncertainty principle, the kinetic energy increases when it is confined in one of the halves (Zurek, 1990).

Some aspects of the original Szilárd cycle are not completely clear, specially the application of the ideal gas equation to the pressure on the piston, which is due to single collisions. Nevertheless, these issues can be resolved and, moreover, the Szilárd engine can be implemented in any system exhibiting a symmetry breaking, like an Ising model (Parrondo, 2001). In fact, there are experimental realizations of the Szilárd engine in a variety of systems: single-electron circuits (Koski et al., 2014; Pekola and Khaymovich, 2019), Brownian particles in optical traps (Roldán et al., 2014), or Brownian rotors in electrostatic potentials (Toyabe et al., 2010).

The Szilárd engine, as the original Maxwell demon, utilizes the information gathered in the measurement to decrease the entropy of the system. While in the Maxwell demon the information involved and the decrease of entropy are difficult to assess, in the Szilárd engine both have a precise value: information is acquired in a single measurement per cycle with two equiprobable outcomes, left (L) or right (R), and the entropy decreases by $k \ln 2$. This is why most of the studies on the connection between thermodynamics and information are based on the Szilárd engine. In fact, the Szilárd engine partially solves the first question mentioned above. Before the measurement, the particle can be in any of the two halves and, after the measurement, it occupies only one. The measurement is equivalent to a compression from a volume V to $V/2$, which reduces the entropy of the gas by $k \ln 2$. Such a compression would need a work $kT \ln 2$, counterbalancing the work (1) extracted in the expansion, but apparently the measurement is able to perform the compression without any energy expenditure.

Thermodynamics of information refines and generalizes this argument (Parrondo et al., 2015). First, by incorporating concepts from information theory that quantify the information acquired in a measurement in a more precise and general way. Second, by realizing that the states resulting from measurements and other processes involving information are in general non-equilibrium states. Hence, thermodynamics of information can be considered as a branch of statistical mechanics that deals with a special class of non-equilibrium states bearing information.

The outline of this article is the following. In Section “Information,” we review the concepts of information theory relevant to thermodynamics, like Shannon entropy and mutual information. We discuss in detail the relationship between Shannon entropy and thermodynamic entropy in Section “Shannon and thermodynamic entropies.” In Section “Second law for feedback processes,” we show how the acquisition of information affects the second law. The resulting modified second law for feedback processes—those that follows a protocol depending on the outcome of a measurement—is the answer to the first question that we have posed above. In Section “Informational states and Landauer’s principle,” we derive the thermodynamic cost of some processes involving information in memories and other information devices, like the celebrated Landauer principle (Landauer, 1961). These costs help us to solve the second question, i.e., the restoration of the original second law in the Szilárd engine and any generic isothermal feedback processes. This is discussed in Section “Restoring the second law,” where we show that feedback processes obey the original second law when one accounts for the cost of measurement and/or restoring the demon’s memory, generalizing Bennett’s analysis of the Szilárd engine (Bennett, 1982). In Section “Information flows,” we introduce a formalism that allows one to study information flows (Allahverdyan and Saakian, 2008; Horowitz and Esposito, 2014) in autonomous Maxwell demons. Finally, in Section “Conclusion: What is information?” we present our main conclusions and discuss the physical nature of information.

Information

In his seminal papers published in 1948 (Shannon, 1948), Shannon introduced a measure of the uncertainty or ignorance that one has about a random object or discrete random variable X , which can be a generic message in a communication channel, a file in a computer, or the microstate of a physical system. Shannon uncertainty, also known as Shannon entropy,³ is defined as

$$S(X) = S[p_X] = -\sum_x p_X(x) \log p_X(x). \quad (2)$$

Here we have introduced two useful equivalent notations, namely, expressing the dependency of the uncertainty S on the random variable X or on its probability distribution $p_X(x)$. Uncertainty can be expressed in bits, if the logarithm in Eq. (2) is in base 2, in nats, if it is the natural logarithm, or in units of thermodynamic entropy if we multiply nats by, for instance, the Boltzmann constant k . In the rest of the article, we will assume that the Shannon entropy is expressed in physical units of energy divided by temperature, without the need of writing explicitly the Boltzmann constant. Finally, for continuous random variables, the sum in (2) must be replaced by an integral (Cover and Thomas, 2006).

It is customary to interpret Shannon uncertainty as a measure of information, and this is indeed appropriate in certain situations. For example, when we consider the information content of a given instance of the random variable X . However, when we talk about information, specially in physics, or, more precisely, about obtaining information from a system, we have in mind an inquiry about the state X of the system, which consists in the measurement of a quantity Y . When we measure Y , we acquire information about X that results in a decrease of its uncertainty. This decrease is precisely the amount of information that Y provides about X :

³In a famous conversation between Shannon and Von Neumann, the latter suggested Shannon to use the name entropy because (2) is similar to the definition of entropy in statistical mechanics and, more importantly, because “nobody really knows what entropy is.” The conversation was reported by Shannon himself but later on he admitted that it probably never took place (Price, 1982).

$$I(X; Y) \equiv S(X) - S(X|Y) \quad (3)$$

which is called *mutual information* (Cover and Thomas, 2006; Shannon, 1948). Here $S(X|Y)$ is the uncertainty of the posterior probability distribution $p_{X|Y}(x|y)$ averaged over the possible outcomes $p_Y(y)$, i.e.,

$$\begin{aligned} S(X|Y) &\equiv \sum_y p_Y(y) \left[- \sum_x p_{X|Y}(x|y) \log p_{X|Y}(x|y) \right] \\ &= - \sum_{x,y} p_{XY}(x,y) \log p_{X|Y}(x|y). \end{aligned} \quad (4)$$

Using the relationship between conditional and joint probabilities (Bayes' formula): $p_{XY}(x,y) = p_{X|Y}(x|y)p_Y(y)$, we can write the mutual information as

$$I(X; Y) = \sum_{x,y} p_{XY}(x,y) \log \frac{p_{XY}(x,y)}{p_X(x)p_Y(y)}. \quad (5)$$

From this expression we can derive a number of interesting properties of the mutual information. First, mutual information is symmetric, i.e., Y provides the same information about X as X provides about Y . Second, using the properties of the logarithm, one can prove from Eq. (5) that $I(X; Y)$ is always positive and vanishes if and only if X and Y are statistically independent (Cover and Thomas, 2006). Hence, mutual information is a measure of the correlation between X and Y . Third, if we measure without error a quantity $Y = f(X)$, then $S(Y|X) = 0$ and $I(X; Y) = S(Y)$. In other words, the information provided by an error-free measurement is the uncertainty of the outcome.

Finally, Eq. (5) allows us to write the mutual information in three different ways:

$$\begin{aligned} I(X; Y) &= S(X) - S(X|Y) \\ &= S(Y) - S(Y|X) \\ &= S(X) + S(Y) - S(X, Y) \geq 0 \end{aligned} \quad (6)$$

where $S(X, Y)$ is the Shannon entropy or uncertainty of the joint probability distribution $p_{XY}(x,y)$. The last equality indicates that correlations make the entropy sub-additive:

$$S(X, Y) = S(X) + S(Y) - I(X; Y). \quad (7)$$

This expression will be useful when we consider the physical nature of Maxwell or Szilárd demons and interpret a measurement as the creation of correlations between the state of the demon and the state of the system.

Shannon and thermodynamic entropies

If Shannon uncertainty is identified as thermodynamic entropy, one immediately obtains from the definition of mutual information (3) that the entropy of a system X decreases by an amount $I(X; M)$ when we measure a quantity M . For instance, in the case of the Szilárd engine with error-free measurements, X is the micro-state of the global system, particle plus bath, which obviously includes the position of the particle, and $M = L, R$ (L for left, and R for right) is the outcome of the measurement, i.e., the half of the container where the particle lies after the insertion of the piston. Since M is a function of X and the two outcomes are equally probable, $I(X; M) = S(M) = k \ln 2$. Thus, the total entropy decreases by $k \ln 2$, and this decrease allows one to extract an energy $kT \ln 2$ from the thermal bath in the form of work by driving quasi-statically the system back to its initial state. This is a similar argument as the one that we sketched in Section "Introduction."

This explanation, however, requires a more careful consideration. The identification of Shannon and thermodynamic entropies is not correct, in general. The main reason is that the Shannon entropy $S[\rho(x,t)]$ of the probabilistic state of a classical system is invariant under Hamiltonian evolution. Here x denotes a micro-state of the system, i.e., the value of the positions and momenta of all its particles, and $\rho(x,t)$ is the probability density of observing a microstate x at time t . The same argument holds for quantum systems, replacing $\rho(x,t)$ by the density matrix $\rho(t)$ and the Shannon entropy by Von Neumann entropy, $\text{Tr}(\rho \ln \rho)$ (Schumacher and Westmoreland, 2010). Here, we will restrict our discussion to classical systems, although it is not difficult to extend it to quantum systems (Esposito et al., 2010).

To observe an increase of Shannon entropy, as dictated by the second law for irreversible processes, one has to consider information losses that degrade the probabilistic state $\rho(x,t)$, like coarse-graining or the inaccessibility of detailed information about certain degrees of freedom.

A second important property of thermodynamic entropy is its connection with the energetics of a process through Clausius equation, which relates the temperature T to the increase of the entropy, δS , and the energy, δE , of a system⁴:

⁴Clausius originally introduced this equation as a definition of entropy. However, it is in fact a definition of temperature for systems at equilibrium, since energy and entropy are more fundamental magnitudes that can be obtained from dynamical properties, like the Hamiltonian and the phase space volume of regions of constant energy.

$$\delta S = \frac{\delta E}{T}. \quad (8)$$

This equation is crucial to find the limitations that the second law imposes on energy extraction from thermal reservoirs. For instance, if a system is in contact with a thermal bath at temperature T , according to Eq. (8) the total entropy production in a process is

$$\Delta S_{\text{tot}} = \Delta S - \frac{Q}{T} \geq 0 \quad (9)$$

where ΔS is the change of entropy in the system and Q is the energy transferred from the bath to the system. If an external agent manipulates the system performing a work W , the change of energy in the system is $\Delta E = Q + W$ and

$$T\Delta S_{\text{tot}} = T\Delta S - \Delta E + W = W - \Delta F \quad (10)$$

ΔF being the increase of free energy, $F = E - TS$, in the system. The second law $\Delta S_{\text{tot}} \geq 0$ for this isothermal process is equivalent to

$$W \geq \Delta F. \quad (11)$$

In particular, for a cycle $\Delta F = 0$ and the inequality, $W \geq 0$, tells us that it is impossible to extract energy from a thermal bath in a cyclic process.

For a system in contact with equilibrium thermal reservoirs, one can solve these two issues—namely, the invariance of Shannon entropy under Hamiltonian evolution and its connection with the energetics of a process—with the two following assumptions that specify the information available to an external observer (Esposito et al., 2010): first, the observer does not have access to the correlations between the system and the baths and, second, the only information about the state of the baths is their average energy. More precisely, the baths are described by thermal states with given average energies. In the case of a single bath with micro-states z , if the actual probabilistic state of the global system at time t is $\rho(x, z; t)$, this loss of information yields an effective state $\rho_{\text{obs}}(x, z; t)$ given by

$$\rho(x, z; t) \rightarrow \rho_{\text{obs}}(x, z; t) = \rho(x, t)\rho_{\text{B,eq}}(z; T(t)) \quad (12)$$

where $\rho(x, t)$ is the marginal probabilistic state of the system

$$\rho(x, t) = \int dz \rho(x, z; t) \quad (13)$$

and $\rho_{\text{B,eq}}(z; T)$ is the thermal state of the bath

$$\rho_{\text{B,eq}}(z; T) = \frac{e^{-\beta H_{\text{B}}(z)}}{Z_{\text{B}}(\beta)}. \quad (14)$$

Here $H_{\text{B}}(z)$ is the Hamiltonian of the bath, $\beta = 1/(kT)$ the inverse temperature, and $Z_{\text{B}}(\beta)$ the partition function. The temperature (t) in (12) is set as the one that verifies

$$\begin{aligned} E_{\text{B}}(t) &\equiv \int dx dz H_{\text{B}}(z) \rho(x, z; t) \\ &= \int dz H_{\text{B}}(z) \rho_{\text{B,eq}}(z; T(t)), \end{aligned} \quad (15)$$

i.e., both distributions have the same average bath energy $E_{\text{B}}(t)$ at any time t .

The replacement of the actual state $\rho(x, z; t)$ by the observable state $\rho_{\text{obs}}(x, z; t)$ solves the two aforementioned issues: the invariance of Shannon entropy under Hamiltonian evolution and the relationship between entropy and energy given by the Clausius equation (8). First, applying (7), we find that the replacement (12) increases the Shannon entropy:

$$S[\rho_{\text{obs}}(x, z; t)] - S[\rho(x, z; t)] = I(X; Z) + \Delta S_{\text{B}} \geq 0 \quad (16)$$

where $\Delta S_{\text{B}} = S[\rho_{\text{B,eq}}(z; T(t))] - S[\rho(z; t)]$. The inequality follows from the positiveness of the mutual information and the fact that the thermal state (14) is the one that maximizes the Shannon entropy under condition (15).

Consider a process where we manipulate the system, whose Hamiltonian $H(x; t)$ is now time-dependent. We also assume that initially system and bath are uncorrelated and the latter is at equilibrium, i.e., $\rho(x, z; 0) = \rho(x, 0)\rho_{\text{B,eq}}(z; T(0))$. Then, $\rho(x, z; 0) = \rho_{\text{obs}}(x, z; 0)$ and, since Shannon entropy is invariant under the Hamiltonian evolution, $S[\rho(x, z; t)] = S[\rho_{\text{obs}}(x, z; 0)]$. Hence, from Eq. (16), we obtain the entropy production in the process:

$$S[\rho_{\text{obs}}(x, z; t)] - S[\rho_{\text{obs}}(x, z; 0)] = I(X; Z) + \Delta S_{\text{B}} \geq 0. \quad (17)$$

This expression reflects the two information losses that we have introduced in (12): $I(X; Z)$ is the information associated to the correlations between the system and the bath, whereas ΔS_{B} is the increase of Shannon entropy that results from replacing the actual state of the bath by a thermal state (Esposito et al., 2010). Each of these terms is positive and we recover a second law for the Shannon entropy $S[\rho_{\text{obs}}(x, z; t)]$. It is interesting to notice that both terms can be relevant in realistic situations, as shown in (Ptaszyński and Esposito, 2019a,b).

Alternatively, the entropy production can also be calculated by using the explicit form of the thermal state (14):

$$S[\rho_{\text{obs}}(x, z, t)] = S[\rho(x, t)] + k\beta(t)E_B(t) + k \ln Z_B(\beta(t)). \quad (18)$$

Since $E_B = -\partial \ln Z_B / \partial \beta$, the time derivative of the Shannon entropy of the observable state can be written as

$$\dot{S}[\rho_{\text{obs}}(x, z, t)] = \dot{S}[\rho(x, t)] + \frac{\dot{E}_B(t)}{T(t)}. \quad (19)$$

Integrating over the whole process with the initial condition discussed above, and taking into account that the bath is large enough so that the change of temperature is negligible,⁵ we finally get

$$S[\rho_{\text{obs}}(x, z, t)] - S[\rho_{\text{obs}}(x, z, 0)] = \Delta S - \frac{Q}{T} \quad (20)$$

where $Q = E_B(0) - E_B(t)$ is the net energy transferred from the bath to the system. From Eq. (17), we conclude that the entropy production, as expressed in Eq. (20), is positive. Thus, we recover the same expression for the entropy production as in (9), i.e., the loss of information implied by (12) is compatible with Clausius equation (8). The standard thermodynamic argument to derive (11) can now be applied to the *non-equilibrium free energy defined as*:

$$\mathcal{F}(\rho, H) \equiv \langle H(x) \rangle - TS[\rho(x)] \quad (21)$$

and yielding a bound to the work needed to complete an isothermal process:

$$W \geq \Delta \mathcal{F}. \quad (22)$$

This can be considered an extension of the second law (11) for isothermal processes involving non-equilibrium states, and reduces to the standard second law if the initial and final states are equilibrium, since the non-equilibrium free energy (21) is equal to the standard equilibrium one for thermal states like (14). Alternatively to our derivation based on information losses, (22) can be directly obtained from a master equation obeying local detailed balance (Esposito and Van den Broeck, 2011), which is the equation that describes systems in contact with reservoirs in the Markovian approximation.

The bound (22) is saturated for operationally reversible process, i.e., for processes where the system visits the same states as in the forward process when the protocol is reversed (Parrondo et al., 2015). This observation puts into question the utility of (22) for generic non-equilibrium states, since any irreversible relaxation to equilibrium prevents the bound to be reached. One strategy to overcome this issue consists in modifying instantaneously the Hamiltonian to convert the initial and final states into equilibrium states, although this protocol is a bit artificial and sometimes unrealizable.⁶ However, the bound (22) can be tight as well for systems with slow and fast degrees of freedom. If there is a large separation of time scales and the fast degrees of freedom are equilibrated during the process, then the inequality (22) is met. As we will see in Section “Informational states and Landauer’s principle,” it turns out that this is the case of many relevant processes involving information.

Second law for feedback processes

In an isothermal feedback process, like the Szilárd engine, the external agent measures a magnitude M at a given time t_m and uses this information to complete an isothermal process. The measurement is characterized by the conditional probability $p_{M|X}(m|x)$, where m is the measurement outcome and x is the microscopic state of the system. This includes error-free measurements, where $p_{M|X}(m|x) = 1$ if $m = m(x)$ and zero otherwise, but it can also describe measurements affected by noise or any other source of inaccuracy. Using the measurement outcome, the observer updates the probabilistic state of the system $\rho_X(x, t_m)$ according to Bayes rule

$$\rho_X(x, t_m) \rightarrow \rho_{X|M}(x|m) = \frac{p_{M|X}(m|x)\rho_X(x, t_m)}{p_M(m)}. \quad (23)$$

Here we are assuming the most common case, where x is a continuous random variable and m is discrete, and use the Latin letter p for probability distributions and the Greek one ρ for probability densities. Nevertheless, the argument can be easily generalized to other cases. For a given outcome m , the updated state $\rho_{X|M}(x|m)$ is in general a non-equilibrium state, even if the state before the measurement, $\rho_X(x, t_m)$, is equilibrium. We see here the first appearance of nonequilibrium states in processes involving information. The unconditional state of the system after the measurement is again

⁵Notice that we have to consider a time-dependent temperature to derive the variation of Shannon entropy in the bath in Eq. (19). However, this variation can be neglected when we integrate this equation, if the heat capacity of the bath is large enough.

⁶Any state $\rho(x)$ can be converted into an equilibrium state by setting the Hamiltonian equal to $H(x) = -kT \ln \rho(x)$. Notice however that such Hamiltonian can be difficult or impossible to realize as, for instance, when $\ln \rho(x)$ is not a quadratic function of velocities.

$$\sum_m p_M(m) \rho_{X|M}(x|m) = \rho_X(x, t_m), \quad (24)$$

i.e., the measurement does not alter the system. In Section “Restoring the second law,” we will establish this as a condition for an ideal classical measurement. Given an outcome m , the free energy after the measurement is

$$\mathcal{F}[\rho_{X|M}(x|m)H(x, t_m)] = \int dx H(x, t_m) \rho_{X|M}(x|m) - TS[\rho_{X|M}(x|m)] \quad (25)$$

where $H(x, t)$ is the Hamiltonian of the system at time t . Averaging over the possible outcomes we get the nonequilibrium free energy after the measurement

$$\mathcal{F}_{\text{post}} = \sum_m p_M(m) \mathcal{F}[\rho_{X|M}(x|m)H(x, t_m)] = \int dx H(x, t_m) \rho(x, t_m) - TS(X|M). \quad (26)$$

Using the definition of mutual information (7), we obtain that, as a consequence of the Bayes update, the nonequilibrium free energy of the system changes as

$$\Delta\mathcal{F}_{\text{meas}} \equiv \mathcal{F}_{\text{post}} - \mathcal{F}_{\text{pre}} = T[(S(X) - S(X|M))] = TI(X; M), \quad (27)$$

where $\mathcal{F}_{\text{pre}} = \mathcal{F}[\rho(x, t_m), H(x, t_m)]$ is the non-equilibrium free energy of the system immediately before the measurement.

We can now apply Eq. (22) to the subprocesses that take place before and after the measurement. The total work in the feedback process is bound as

$$W_{\text{fb}} \geq \mathcal{F}_{\text{fin}} - \mathcal{F}_{\text{post}} + \mathcal{F}_{\text{pre}} - \mathcal{F}_{\text{init}} = \mathcal{F} - \Delta\mathcal{F}_{\text{meas}} \quad (28)$$

where $\Delta\mathcal{F} = \mathcal{F}_{\text{fin}} - \mathcal{F}_{\text{init}}$ and the subscripts, init, pre, post, fin, indicate respectively the states at the different stages of the process: initial and final, and immediately before and after the measurement (see Fig. 3). Combining (27) and (28), we finally obtain

$$W_{\text{fb}} \geq \Delta\mathcal{F} - TI(X; M) \quad (29)$$

which is the second law for feedback processes. This result was derived by Sagawa and Ueda for classical and quantum systems (Sagawa and Ueda, 2008), although the relevance of mutual information in thermodynamics was first pointed out by Lloyd and Touchette (Lloyd, 1989; Touchette and Lloyd, 2000). It indicates that the work necessary to complete a process decreases by an amount $TI(X; M)$ if we use the information gathered in the measurement. In particular, for a cycle the work can be negative, i.e., we can extract a work $W_{\text{extract}} = -W_{\text{fb}}$ at least equal to $TI(X; M)$. The Szilárd engine, where $I(X; M) = k \ln 2$ is an explicit example that saturates the bound.

Notice that, due to (24), the unconditional non-equilibrium free energy of the system does not change in the measurement. The mutual information $I(X; M)$ in (27) and (29) appears because we average the conditional entropy over $p_M(m)$. The reason of averaging in this way is that, in a feedback process, the protocol depends on the outcome m , and so does the work. The bound (29) applies to the average work W_{fb} over all possible outcomes and protocols, each one obeying (22). If the information provided by the measurement is not used in the protocol from t_m to the final time of the process, then we recover the standard second law (22) with equilibrium free energies.

The bound (29) does not resolve the problem of reconciling the Szilárd engine with the original second law. However, it is an important result because it establishes a benchmark to the work that can be extracted in a feedback process. It also indicates that the mutual information $I(X; M)$ is a thermodynamic resource and can be used to define efficiencies for information and hybrid engines (Saha et al., 2021; Schmitt et al., 2015) and to compare the performance of information motors and of chemical or thermal machines (Horowitz et al., 2013). It is also interesting to explore which protocols saturate the bound (29). It is found that this happens for operationally reversible processes, those which visit the same states when the action of the external agent is reversed (Horowitz and Parrondo, 2011a). Notice however that the notion of reversibility of feedback processes requires a more careful discussion, since it is not trivial to define the time reversal of a measurement (Horowitz and Parrondo, 2011b; Horowitz and Vaikuntanathan, 2010).

The second law (29) can be further refined by deriving fluctuation theorems. These theorems are exact equalities that hold for any process even far from equilibrium, and from which the second law can be obtained as a corollary (Horowitz and Vaikuntanathan, 2010; Ponmurugan, 2010; Sagawa and Ueda, 2009, 2010, 2012).

Fig. 3 Scheme of a basic feedback process with a single measurement.

Informational states and Landauer's principle

Information devices, like memories, processors, or the biochemical machinery of DNA and RNA, are systems that can adopt different informational states that have a long lifetime and are interchangeable. These states are, for example, the bits in a hard drive, which can be 0 or 1, or the bases of DNA, which can be any of the four nucleotides: cytosine, guanine, adenine or thymine.

These two properties, long lifetimes and interchangeability, imply some kind of effective symmetry breaking in the system: its phase space is partitioned into several regions where the system remains for a very long time. Each region is an informational state and the system is no longer ergodic in the whole phase space. Here, we refer to an effective lack of ergodicity when there is a huge separation between the time scales of the dynamics within the regions and of the jumps between regions. This type of effective ergodicity breaking occurs due to phase transitions in finite systems or to the presence of high energy barriers with a negligible probability to be crossed. A paradigmatic example is a Brownian degree of freedom in a double well potential, like the one depicted in Fig. 4.

In general, the phase space Γ of an information device is partitioned into a number of regions Γ_m , with $m = 1, 2, \dots, \mathcal{M}$. We will assume that the dynamics within each region is very fast and that the system is in local equilibrium within every Γ_m . On the other hand, the system can be in any of the informational states with certain probability p_m that depends on the history, measurements, etc. We show an explicit example in Fig. 4, based on a Brownian particle or degree of freedom in a double well potential. By raising the barrier far above kT , we create a memory from (a) to (b). If the potential is symmetric, each informational state $m = L, R$ is populated with the same probability $p_L = p_R = 1/2$ and the system is in global equilibrium. However, if we change the energy of the wells, as in (c), populations do not change due to the high barrier but the equilibrium probabilities $p_{R,L}^{\text{eq}}$ depart from $1/2$. Hence, the system is no longer in global equilibrium. The informational state can also change due to a measurement, as in the transition from (c) to (d).

If the device is at temperature T , the state of the system is then given by

$$\rho(x) = \sum_m p_m \frac{e^{-\beta H(x)}}{Z_m} \chi_m(x) \quad (30)$$

where $x \in \Gamma$ is a micro-state, $H(x)$ is the Hamiltonian, $\chi_m(x)$ is the index function of Γ_m , i.e., $\chi_m(x) = 1$ if $x \in \Gamma_m$ and zero otherwise, and Z_m is the restricted partition function

$$Z_m \equiv \int_{\Gamma_m} dx e^{-\beta H(x)}. \quad (31)$$

The probability distribution $\{p_m\}$, with $m = 1, 2, \dots, \mathcal{M}$ is arbitrary and defines a probabilistic informational state. The main characteristic of the information device is that it can adopt any probabilistic informational state and that an external agent can drive the system, as in Fig. 4, from one probabilistic informational state to another, writing or processing information in the device. A special probabilistic informational state is the one corresponding to global equilibrium $p_m = Z_m/Z$, where $Z = \sum_m Z_m$ is the global partition function.

The energetics of processes involving informational states can be analyzed using the non-equilibrium free energy (21), which for state (30) reads

Fig. 4 Informational states of a Brownian degree of freedom in a bistable potential. The rise of the barrier from (a) to (b) illustrates the creation of information (Roldán et al., 2014), whereas (c) and (d) show non-equilibrium probabilistic informational states, which are the result of the history and of a measurement, respectively.

$$\mathcal{F}(\rho, H) = \sum_m p_m F_m - TS(p_m) \quad (32)$$

where $F_m = -kT \ln Z_m$ is the restricted free energy and $S(p_m)$ is the Shannon entropy of the probabilistic informational state. As already mentioned, the non-equilibrium free energy equals the equilibrium one, $\mathcal{F}(\rho, H) = -kT \ln Z$ if the system is in global equilibrium. For a symmetric memory where $F_m = F_{\text{local}}$ is the same for all informational states m , we have

$$\mathcal{F}(\rho, H) = F_{\text{local}} - TS(p_m). \quad (33)$$

Now suppose that we manipulate a symmetric memory driving the system isothermally from a distribution p_m to p'_m . If the initial and final restricted free energies are equal, then the work needed to complete the process is bound by

$$W \geq T[S(p_m) - S(p'_m)]. \quad (34)$$

This equation tells us that we have to perform work to order a memory, $S(p'_m) < S(p_m)$, whereas we can extract work by disordering a symmetric memory $S(p'_m) > S(p_m)$.

Landauer's principle is a special case of Eq. (34). Landauer considered a simple process where a binary symmetric memory is initially in a random state $p_0 = p_1 = 1/2$, with $S(p_m) = k \ln 2$ and is driven to the informational state 0 with probability one, i.e., $p'_0 = 1$ and $p'_1 = 0$, with zero Shannon entropy. This process is called restore-to-zero, and is usually considered as the erasure of the initial random bit, although it is more appropriate to call it overwriting, since the initial unknown bit is replaced by a given one, 0 in our example. The work needed to complete Landauer's overwriting is

$$W \geq kT \ln 2 \quad (35)$$

which is the so-called Landauer's principle. The Landauer principle has been confirmed experimentally in different systems, like Brownian particles in optical traps (Berut et al., 2011) (see Proesmans et al., 2020 for a discussion on experimental results on the energetics of overwriting at finite speed). Landauer's overwriting is a special case of a logically irreversible operation, since the initial informational state of the memory (input) cannot be recovered from the final one (output). It is a common misunderstanding to interpret Landauer's principle as if logical irreversibility implied thermodynamic irreversibility. This is not true. If inequality (35) is met, the overwriting process is still logically irreversible but thermodynamically reversible because the decrease of entropy in the system is compensated by the increase of entropy in the thermal bath due to heat dissipation. Hence, the total entropy production is zero. See (Sagawa, 2014) for a detailed discussion on the relation between thermodynamic and logical reversibility.

On the other hand, if a memory has a low Shannon entropy, one can extract work by disordering it. The thermodynamics of these information reservoirs that can act as thermodynamic resources has been analyzed in detail by Barato and Seifert (2014), and by Wolpert (2019). Mandal and Jarzynski (2012) have devised a concrete realization of work extraction from an ordered memory using a kinetic model that reads the content of a tape.

Restoring the second law

We can now address the question of restoring the original second law in the Szilárd engine by considering the physical nature of the demon, who must possess a memory to register the measurement outcomes and is subjected to the thermodynamic limitations discussed in the previous section.

First, let us consider the energetics of a measurement. An ideal classical measurement consists of the interaction between a system and a measurement apparatus, which fulfills the following requirements: (i) system and apparatus are initially uncorrelated; (ii) the system is not affected by the interaction; and (iii) system and apparatus do not interact before and after the measurement, i.e., the Hamiltonian of the global system is $H_{\text{sys}}(x) + H_{\text{app}}(y)$, where x and y are microstates of the system and the apparatus, respectively. Let Y and Y' be the random variables denoting the state of the apparatus before and after the measurement, respectively, and $p_{M|X}(m|x)$ the conditional probability characterizing the measurement. We will further assume that the outcome is a function of the apparatus micro-state $M = m(Y')$ and that all the information about X is provided by the measurement outcome, i.e., $\rho_{X|Y}(x|y) = \rho_{X|M}(x|m(y))$.

If the initial state of the global system immediately before the measurement is

$$\rho_{XY}(x, y) = \rho_X(x) \rho_Y(y) \quad (36)$$

with non-equilibrium free energy

$$\mathcal{F}(X, Y) = \mathcal{F}(X) + \mathcal{F}(Y), \quad (37)$$

then the state after the measurement is

$$\rho_{XY'}(x, y) = \sum_m \rho_X(x) p_{M|X}(m|x) \rho_{Y'|M}(y|m) \quad (38)$$

where $\rho_{Y'|M}(y|m) = \rho_Y(y)/p_M(m)$ if $m = m(y)$ and zero otherwise. The marginal probability density for the state of the system $\rho_X(x)$ does not change as a consequence of the measurement. This is why we can still denote the random variable corresponding to the

Fig. 5 Sketch of the operations in a feedback cycle.

state of the system as X , whereas the apparatus changes from Y to Y' (see Fig. 5). With these assumptions, it is not hard to prove that $I(X; Y') = I(X; M)$, since Y' provides information about X through the outcome M . Since the energy of the system does not change due to the measurement, the non-equilibrium free energy of the global system (X, Y') immediately after the measurement can be written as

$$\begin{aligned}\mathcal{F}(X, Y') &= \mathcal{F}(X) + \mathcal{F}(Y') + TI(X; Y') \\ &= \mathcal{F}(X) + \mathcal{F}(Y') + TI(X; M)\end{aligned}\quad (39)$$

where we have used Eq. (7) to express the total Shannon entropy $S(X, Y')$ in terms of the mutual information $I(X; Y')$. Hence, the work needed to complete the measurement is

$$W_{\text{meas}} \geq \Delta\mathcal{F} = \Delta\mathcal{F}_Y + TI(X; M) \quad (40)$$

where $\Delta\mathcal{F}_Y = \mathcal{F}(Y') - \mathcal{F}(Y)$. Since $I(X; M)$ is positive, we see that measuring or, more generally, creating correlations between two systems, increases the free energy and, if not counterbalanced by $\Delta\mathcal{F}_Y$, needs work and heat dissipation to be completed.

As discussed in Section “Second law for feedback processes,” the demon can extract a work $W_{\text{extract}} = -W_{\text{fb}}$ with $W_{\text{fb}} \geq TI(X; M)$ if he uses the information acquired in the measurement in a cyclic process, where the system is driven back to its initial state X .

However, to complete the cycle, the apparatus must be also driven to its initial state Y . In doing so, the demon must perform a work

$$W_{\text{reset}} \geq \mathcal{F}(Y) - \mathcal{F}(Y') = -\Delta\mathcal{F}_Y. \quad (41)$$

The total work in the process is then

$$W_{\text{tot}} = W_{\text{meas}} + W_{\text{fb}} + W_{\text{reset}} \geq 0. \quad (42)$$

Hence, the validity of the second law for feedback processes is restored when the entropy costs of measurement and/or resetting the demon’s memory are taken into account. This is the generalization of Bennett’s analysis of the Szilard engine. Bennett discussed in (Bennett, 1982) a realization of the Szilard engine where $W_{\text{meas}} = 0$ and the demon must overwrite the outcome of the measurement performing a work $kT \ln 2$, as dictated by Landauer’s principle. This is achieved if $\Delta\mathcal{F}_Y = -TI(X; M)$.

From the previous discussion, we see that the Szilárd engine can be interpreted as a relatively simple exchange between work and the free energy $TI(X; M)$ stored in the correlations between the system and the demon. For instance, if $\Delta\mathcal{F}_Y = 0$, the engine consists of creating correlations in the measurement, an operation that requires a work $TI(X; M)$ and increases the free energy by the same amount, and then destroying these correlations in the feedback, where the same amount of work is now extracted.

The previous discussion can be presented in terms of entropy, instead of free energy, and extended to continuous time. Consider now that both the system and the demon are random processes, $X(t)$ and $Y(t)$, respectively. The time derivative of Eq. (7) reads

$$\dot{S}(X(t), Y(t)) = \dot{S}(X(t)) + \dot{S}(Y(t)) - \dot{I}(X(t); Y(t)) \quad (43)$$

and the total entropy production can be written as

$$\dot{S}_{\text{prod}} = \dot{S}(X(t)) + \dot{S}(Y(t)) - \dot{I}(X(t); Y(t)) + \dot{S}_{\text{env}}(t) \geq 0 \quad (44)$$

where $\dot{S}_{\text{env}}(t)$ is the change per unit of time of the entropy of the environment at time t . For instance, if the system and/or the demon are in contact with several thermal baths at different temperatures T_i , then $\dot{S}_{\text{env}}(t) = -\sum_i \dot{Q}_i(t)/T_i$, where $\dot{Q}_i(t)$ is the energy transfer per unit of time from the i -th bath to the system.

The scheme of Fig. 5 can be seen as the different stages of a continuous evolution. In the measurement, the system does not change, hence $\dot{S}(X(t)) = 0$ and the integration of (44) yields

$$\Delta S_Y - \Delta I + \Delta S_{\text{env}}^{(\text{meas})} \geq 0. \quad (45)$$

Here, ΔI is the mutual information developed in the measurement. Notice however that the measurement in this description is any interaction between X and Y that creates correlations between the two systems, keeping X constant. During feedback, the demon does not change, hence $\dot{S}(Y(t)) = 0$. If the feedback process is cyclic, $\Delta S_X = 0$, and if all the correlations created during the measurement are destroyed, then

$$\Delta I + \Delta S_{\text{env}}^{(\text{fb})} \geq 0. \quad (46)$$

Finally, during the demon resetting:

$$-\Delta S_Y + \Delta S_{\text{env}}^{(\text{reset})} \geq 0. \quad (47)$$

The sum of the three inequalities (45)–(47) yields the standard second law for the total entropy production

$$S_{\text{prod}} = \Delta S_{\text{env}}^{(\text{meas})} + \Delta S_{\text{env}}^{(\text{fb})} + \Delta S_{\text{env}}^{(\text{reset})} \geq 0. \quad (48)$$

Therefore, Eq. (44) comprises all our discussion on the Szilárd engine but also extends to generic dynamics where two systems evolve in time creating and destroying correlations (Horowitz and Esposito, 2014).

Information flows

The previous discussion holds for an arbitrary evolution. However, for (44) to be meaningful, the evolution must be driven by an external agent (without feedback), which switches on and off the coupling between system and demon in the measurement and resets the demon to its initial state. Otherwise the global system reaches a steady state where all terms in Eq. (44) vanish in average. Still, it is interesting to interpret as information engines autonomous motors that work in a non-equilibrium stationary state (NESS). For this purpose, it is useful to introduce the notion of *information flows* (Allahverdyan et al., 2009; Horowitz, 2015; Horowitz and Esposito, 2014):

$$\dot{I}_X(t) = \lim_{\tau \rightarrow 0^+} \frac{I(X(t+\tau); Y(t)) - I(X(t); Y(t))}{\tau} \quad (49)$$

and

$$\dot{I}_Y(t) = \lim_{\tau \rightarrow 0^+} \frac{I(X(t); Y(t+\tau)) - I(X(t); Y(t))}{\tau}. \quad (50)$$

In the NESS, $\dot{I}_X(t) + \dot{I}_Y(t) = \dot{I}(X(t); Y(t)) = 0$, and $\dot{I}_X(t) = -\dot{I}_Y(t)$. This is why these quantities can be considered flows of a conserved quantity, although this interpretation is valid only in the stationary regime.

If $\dot{I}_X(t)$ is positive then the motion of X , with Y fixed, increases the correlation between the two systems. Accordingly to our discussion in the previous section, we can interpret it as X measuring Y . On the other hand, if $\dot{I}_X(t) < 0$, the motion of system X destroys correlations, like a demon using information to complete a feedback process and converting the free energy stored in correlations into work.

When each system is coupled to separate baths, one can derive a second law for the entropy production in the stationary regime due to the dynamics of each system, X or Y :

$$-\dot{I}_X + \dot{S}_{\text{env}}^X \geq 0; \quad \dot{I}_X + \dot{S}_{\text{env}}^Y \geq 0 \quad (51)$$

where $\dot{S}_{\text{env}}^{X,Y}$ is the entropy increase in the reservoir connected to system X and Y , respectively. These partial second laws have been derived for multipartite continuous and discrete Markovian systems (Horowitz and Esposito, 2014; Horowitz, 2015) and they allow us to analyze the energetics of autonomous motors from the point of view of information flows. In Horowitz and Esposito (2014), apply it to two coupled quantum dots in contact with reservoirs with different temperatures and/or chemical potentials, a device that can operate as a pump or a refrigerator. Information flows and Eq. (51) do not only provide an interesting interpretation of one of the dots acting as a Maxwell demon on the other, but are also useful to derive limitations to the energetics that go beyond the application of the standard second law to the whole device. It is possible as well to evaluate separately the efficiency of the exchange

between entropy and information in each dot (Horowitz and Esposito, 2014). See also (Rosinberg and Horowitz, 2016) for an example of continuous classical degrees of freedom and (Ptaszyński and Esposito, 2019a,b) for an extension to quantum systems.

Information flows are related to other magnitudes that quantify the exchange of information among different systems. In the context of data analysis, Schreiber introduced the so-called *transfer entropy* (Schreiber, 2000) to find causal relationships between two time series, whereas Liang and Kleeman (2005) studied similar information transfers in dynamical systems. Although transfer entropies have been criticized as a tool to find causal relations (James et al., 2016), they have been proven useful to derive fluctuation theorems in bipartite systems (Hartich et al., 2014) and general causal networks (Ito and Sagawa, 2013). The relationship between transfer entropies and information flows has been studied in detail in (Allahverdyan et al., 2009; Cafaro et al., 2016; Horowitz, 2015; Horowitz and Sandberg, 2014; Kiwata, 2022).

Conclusion: What is information?

Thermodynamics of information makes a precise assessment of the effect of information on the second law and clarifies the thermodynamic cost of information operations. The key concept is the mutual information between the state of a system and the outcome of a measurement since, as shown in (7), it is equal to the decrease of Shannon entropy due to the measurement, but also to the difference, due to correlations, between the entropy of a composite system and the sum of the entropies of its parts. To relate Shannon entropy with the energetics of a process, we have introduced in Section “Shannon and thermodynamic entropies” the loss of information that one would expect when a system is in contact with reservoirs at equilibrium. This analysis yields the definition of another relevant concept: the non-equilibrium free energy (21), which determines the minimal work necessary to complete an isothermal process connecting non-equilibrium states.

We have shown that the states relevant to information processing are out of equilibrium, either because they are the result of a Bayesian update, like (23), or because they describe memories with arbitrary probabilistic informational states, as in (30). In both cases, non-equilibrium free energy establishes limitations to the energetics of isothermal processes involving information. These limitations are extensions of the second law to informational non-equilibrium states. In this framework, information appears as a novel thermodynamic resource and those extensions of the second law are indispensable to assess the efficiency of its exploitation.

We have also used non-equilibrium free energy to prove that the Szilárd engine and any isothermal feedback process are compatible with the standard second law of thermodynamics. For this purpose, we have considered the physical nature of the demon and, in doing so, we not only solve the fundamental question posed by Maxwell more than one century ago, but open as well the possibility of interpreting certain devices like motors, refrigerators and other chemical or thermal machines, as transducers that convert information into work and vice-versa. For this interpretation to hold, thermal fluctuations and correlations must be essential ingredients in the functioning of these machines. This is why information thermodynamics is closely related to—or can even be considered as a branch of—a recent field of research, stochastic thermodynamics, which studies the energetics of processes at the micro- and nano-scale, incorporating fluctuations (Peliti and Pigolotti, 2021; Sekimoto, 2010).

In this article, we have restricted ourselves mostly to classical systems. The reason is that, in an isothermal process, a quantum system rapidly adopts a state which is diagonal in the eigenbasis of the Hamiltonian. In these scenarios, coherences are lost and the system can be studied with the same tools as those developed for classical systems. In fact, most of the concepts that we have introduced in the previous sections can be straightforwardly extended to quantum systems. Nevertheless, in the last years there has been an increasing interest in phenomena that combine in a nontrivial way quantum and thermal effects (Anders and Esposito, 2017). Zurek (1990) and Lloyd (1997) already found distinctive aspects of the quantum Szilárd engine and Kim et al explored the effect of quantum statistics in multiparticle Szilárd cycles with bosons and fermions (Kim et al., 2011). The mutual information between quantum systems can be split into a classical and a purely quantum part due to entanglement, known as *quantum discord*, and whose role in quantum Maxwell demons have been analyzed in (Park et al., 2013; Zurek, 2003). Finally, some setups involving the coupling between two quantum states can be interpreted as Maxwell demons that use information. This is the case of the experiment reported in (Cottet et al., 2017) where the coupling between a transmon qubit and the radiation in a microwave cavity can be used to extract work.

From a more fundamental point of view, the interplay between information and matter is nowadays considered a crucial issue for our understanding of the physical world. In 1992, Wheeler summarized in the celebrated lemma “it from bit” (Wheeler, 1995) the idea that information is the basic concept upon which every physical theory should be built. Since then, a number of physicist and philosophers have attempted to follow this research program. Thermodynamics of information, on the other hand, pursues more modest goals but it does provide some insight on how information is implemented in physical systems. In this article we have seen two basic aspects of the physical nature of information. The first one is the characteristics of the informational states introduced in Section “Informational states and Landauer’s principle,” namely, long lifetimes and interchangeability. The second one is the interpretation of information in feedback engines as an exchange between work and the free energy $TI(X; Y)$ stored in the correlations between two systems, X and Y . Each of these two aspects has yielded interesting lines of research. The first one explores the energetics of processes in systems where there is a huge separation of time scales (Roldán et al., 2014), whereas the second one has inspired the notion of information flows in autonomous systems (Horowitz and Esposito, 2014). We believe that any reflection about information as a fundamental concept in physics should account for and/or utilize these two aspects.

Acknowledgments

This article summarizes work done over more than 10 years and it would not have been possible without the interaction with many colleagues, friends, and students from different summer schools. A special mention deserve Jordan Horowitz, with whom I have done a great part of my contributions to the field, and Takahiro Sagawa, who has been one of the most active and influencing researchers in the recent application of stochastic thermodynamics to information processing. Together with Jordan and Takahiro, we wrote a review article (Parrondo et al., 2015), which shaped most of my ideas on the thermodynamics of information. The preparation of this review has been financially supported by the Spanish Government (Grant FLUID. Ref: PID2020-113455GB-I00) and the Foundational Questions Institute (FQXi) under the program “Information as Fuel” (Grant NANOQIT. Ref FQXi-IAF19-01). I appreciate the hospitality of Natalia Ares at University of Oxford and discussions with the whole NANOQIT team on the content and organization of this article. Finally, I am indebted to Jordan Horowitz, Takahiro Sagawa, and Massimiliano Esposito for their careful reading of the article and their helpful suggestions.

Abstract

We introduce and review briefly the phenomenon of quantum annealing and analog computation. The role of quantum fluctuation (tunneling) in random systems with rugged (free) energy landscapes having macroscopic barriers are discussed to demonstrate the quantum advantage in the search for the ground state(s) through annealing. Quantum annealing as a physical (analog) process to search for the optimal solutions of computationally hard problems are also discussed.

Introduction

The idea of computation by decomposing the entire operation into elementary operations like addition, subtraction, etc., and eventually recasting the problem into just number crunching arithmetic, has been quite successful and popular. This has been possible because of the feasibility of binary digitization of the real numbers and availability of ever faster electronic logic gates (AND, OR, XOR, NOT, etc.).

The development and success of digital computers eclipsed the development of the analog computers, based on the dynamics of physical systems. Imagine a bowl on the table and you need to 'locate' its bottom point. Of course, one can calculate the local depths (from a reference height) everywhere along the inner surface of the bowl and search for the point where the local depth is maximum. However, as every one would easily guess, a much simpler and practical method could be to allow rolling of a marble ball along the inner surface of the bowl and wait for its resting location or position. Here, the physics of the forces of gravity and friction allows us to 'calculate' the location of the bottom-most (or minimum energy) point in an analog way! In principle, a similar trick would work for cases where the internal surface of the bowl has modulations, keeping the surface contour or the landscape valleys all tilted toward the same bottom point location. Problem comes when these valleys get separated by 'barriers', high enough.

Computationally hard problems, e.g., search of the ground state(s) of N -spin Sherrington-Kirkpatrick (SK) spin glass system (Sherrington and Kirkpatrick, 1975) involves locating the minima in a rugged landscape of size 2^N , or exponential in N . The (free) energy landscape becomes rugged with occasional barriers of N order, meaning that by flipping a countable few spins one can not get out of the local minimum. For that, one needs to flip a macroscopic number (of order N) to get out of the local minima. The same is true for the N -city Traveling Salesman Problem (see e.g., Kirkpatrick et al., 1983) where one has to find the minimum cost (or travel distance) tours for visiting all the cities, from among the $N!$ order possible tours. Here also, perturbing a tour of higher travel length (cost function), by rearranging the local visit sequence (of a few cities), will not lead to success and one has to take a global view of modifying the sequence of visits to a finite fraction of the cities (effectively by overcoming N order cost function barriers). Generally, for such minimum cost search from among $\exp(N)$ or higher configurations (or tours), often separated by N -order (energy or cost function) barriers, the search time can not be bounded by any polynomial in N (NP-hard problems).

Simulated (classical) annealing

In the seminal paper by Kirkpatrick et al. (1983), a novel stochastic technique was proposed based on the metallurgical annealing technique: To search for the optimized cost (energy of the ground state 'crystal') at eventually vanishing noise (or temperature T), one starts from a high noise (T) 'melt' phase, and tune slowly the noise level. In this 'simulated noise' tuning process, the (classical) noise at any intermediate level of annealing allows for the acceptance with (Gibbs-like) probability determined by the change in cost or energy (scaled by the noise factor) of even higher cost (energy) fluctuations. As the noise level (T) is slowly reduced during the annealing, the gradually decreasing probability of accepting higher cost values allows the system to come out of the local minima valleys and to settle eventually in the 'ground state' of the system with lowest cost (energy) value. It has been a remarkably successful trick for 'practical' computational solutions of a large class of multi-variable optimization problems in reasonable

convergence time. For NP-hard problems, however, the search or convergence time for reaching the lowest cost state or configuration grows exponentially with N .

The bottleneck could be identified soon. Extensive study of the dynamics of frustrated random systems like the SK model showed that its (free) energy landscape (in the spin glass phase) is extremely rugged and the barriers, separating the local valleys, often become N order for a N -spin glass. Same is true for N -city Traveling Salesman Problem. In the macroscopic size limit (N approaching infinity) therefore such systems become (effectively) non-ergodic or localized and the classical (thermal) fluctuations, like that in the simulated annealing, fail to help the system to come out of such high barriers (at random locations or configurations, not dictated by any symmetry) as the escape probability is of order $\exp(-N/T)$ only. Naturally the annealing time (inversely proportional to the escape probability), to get the ground state of the N -spin SK model, can not be bounded by any polynomial in N .

Quantum tunneling advantage for annealing

The indication (Ray et al., 1989) was that quantum fluctuations in the SK model can perhaps lead to some escape routes to ergodicity or quantum fluctuation induced delocalization (at least in low temperature region of the spin glass phase) by allowing tunneling through such macroscopically tall but thin barriers which are difficult to scale using classical fluctuations. This is based on the argument that escape probability (see e.g., the discussion in Mukherjee and Chakrabarti (2015)) due to quantum tunneling, from a single valley with single barrier of height V and width w , scales as $\exp(-\sqrt{V}w/\Gamma)$; where Γ represents the quantum fluctuation strength (or tunneling probability), while the classical (escape) probability is of order $\exp(-V/T)$ with T denoting the temperature of the system (see Fig. 1). This extra handle through the barrier width w (absent in the classical escape probability) helps in a major way in its vanishing limit. Indeed, for a single narrow ($w \rightarrow 0$) barrier of height N , when the tunneling parameter Γ is slowly tuned to zero, the annealing time to reach the ground state or optimized cost, will become N independent! It has led to some important clues. Of course, complications (due to localization) may still arise for many such barriers at random locations.

In the Quantum Annealing scheme, the cost function of a multivariable optimization problem is mapped on to the energy function corresponding to a classical (frustrated) Hamiltonian (H_0). A time dependent quantum (non-commuting) kinetic term ($\Gamma(t)H'$) is then added to the system. As H' does not commute with the H_0 , it provides quantum dynamics to the overall system represented by the time dependent Hamiltonian $H(t) = H_0 + \Gamma(t)H'$ and the evolution of the system is given by the solution of the time dependent Schrödinger equation of the system

$$i\hbar \frac{\partial \psi}{\partial t} = [\Gamma(t)H' + H^0]\psi.$$

If $\Gamma(0)$ is taken to be very large, then ψ starts as the ground state of H' , which is assumed to be known. As $\Gamma(t)$ starts decreasing slowly enough, following the quantum adiabatic theorem, the system will then be carried into the ground state of the instantaneous total Hamiltonian. At the end of the annealing schedule the kinetic term becomes zero ($\Gamma = 0$). Hence, one would expect the system to arrive at (one of) the ground state(s) of H_0 , thereby giving the optimized value of the original cost function. We represent schematically the advantage of quantum annealing, compared to the classical one, using Fig. 2. This was first demonstrated in Kadowaki and Nishimori (1998) for random spin systems, by numerical solutions of the above Schrödinger equation for such systems. Indeed, the numerical results reported there for the annealing of a frustrated magnetic system (with less than 10 spins), are shown in Fig. 3, indicating the clear advantage of tuning the quantum fluctuation, compared to the classical (thermal) one. The

Fig. 1 Schematic diagram suggesting the advantage of quantum tunneling over thermal hopping across a potential barrier. For kinetic energy (E) greater than the barrier potential (V), compared to those in regions (A) and (C), the plane wave functions ($\psi(x) = A \exp(ikx)$ or $\psi(x) = A' \exp(ik'x)$) are indicated with (real) wave vectors $k = \sqrt{E - V} \simeq k'$ in the two regions respectively. For region (B), the wave vector becomes imaginary (as $V > E$) and the consequent damping of the amplitude A in region (A) to A' in region (C), occurs while passing through region (B). For V of order N and E of order $N\Gamma$, the barrier transmission probability $(A'/A)^2$ scales as $\exp(-w\sqrt{N(1-\Gamma)}) \sim \exp(-w\sqrt{N/\Gamma})$.

Fig. 2 Optimizing the cost function of a computationally hard problem (for example, search for the ground state energy of a spin glass or for the minimum travel distance in a traveling salesman problem), one has to get out of a shallower local minimum (indicated here by the configuration C of the spins in a spin glass or of a travel route of the salesman), to reach a deeper minimum (indicated here by C'). This requires jumps or tunneling like fluctuations in the dynamics. Classically one has to jump over the energy or the cost barriers separating them, while (as indicated in Fig. 1) quantum mechanically one can tunnel through the same. With increasing barrier height, thermal jump becomes extremely difficult. However, if the barrier is narrow enough, quantum tunneling can help the search problem much easily.

Fig. 3 Time dependence of the overlaps P (with the ground state) of the frustrated model with $\Gamma(t) = T(t) = 3/\sqrt{t}$ for classical and quantum annealing (subscripts 'SA' and 'QA' indicate simulated annealing and quantum annealing respectively, whereas superscript 'st' corresponds to quasistatic solution). From Kadowaki T and Nishimori H (1998) Quantum annealing in the transverse Ising model. *Physical Review E* 58: 5355.

successive experimental (Brooke et al., 1999) and theoretical (Farhi et al., 2001; Santoro et al., 2002) demonstrations led to the emergence of the field (Das and Chakrabarti, 2008).

Quantum annealing in spin glasses

Using Suzuki-Trotter mapping of the quantum SK model to the effective classical spin model, Monte Carlo studies were conducted and annealing through ergodic and nonergodic regions of the model was studied (Mukherjee and Chakrabarti, 2019). Determination of the phase diagram of the quantum SK model, employing the Monte Carlo simulation (at finite temperatures) and exact diagonalization technique (at zero temperature) revealed some interesting features. To extract the critical behavior at finite temperatures, different sizes (number of Ising spins ranging from 20 to 180) were considered in (Mukherjee and Chakrabarti, 2019), keeping constant the ratio of Trotter size and the effective dynamical size of the number of spins. At zero temperature,

Fig. 4 Phase diagram of quantum SK spin glass model as estimated from the Monte Carlo simulation and exact diagonalization. The spin glass and paramagnetic phases are denoted by SG and PM respectively. The data points at $T = 0$ and $\Gamma = 0$ are associated with the purely quantum and classical phase transitions, respectively. The two observed different critical behaviors of the system are indicated by blue (with the Binder cumulant g_c near 0 and the correlation length exponent value near 1/4) and by yellow (with critical Binder cumulant g_c near 0.22 and correlation length exponent value near 1/2) lines. The crossover in the critical behavior occurs around $T = 0.49$ and $\Gamma = 1.31$. From Mukherjee S and Chakrabarti BK (2019) On the question of ergodicity in quantum spin glass phase and its role in quantum annealing. *Journal of the Physical Society of Japan* 88: 061004.

however, the maximum system size (for diagonalization study) had been of order 20 only. They found that from the quantum transition point ($T = 0, \Gamma_c \simeq 1.63$) to almost the point ($T = 0.45, \Gamma = 1.33$), the critical Binder cumulant value remained vanishingly small (it can indeed effectively vanish even for non-Gaussian fluctuation-induced phase transitions). In this range of the phase boundary, they found the correlation length exponent to be about 1/4 from the data collapse of Binder cumulant plots. In the rest of the phase boundary, the critical Binder cumulant value is about 0.22 and they observed a satisfactory data collapse with the correlation length exponent equal to 1/2. These two different values of the critical Binder cumulant and the correlation length exponent for the two different parts of the phase boundary indicate the classical to quantum crossover (at $T \simeq 0.49$ and $\Gamma \simeq 1.31$; see Fig. 4) occurs at a non-vanishing value of temperature in the quantum SK model.

Unlike in the pure system (also in non-frustrated random system), where the free-energy landscape is smoothly inclined toward the global minima (Landau scenario), in the SK spin glass the landscape is extremely rugged. In particular, the local minima are often separated by system size dependent energy barriers which induce nonergodicity and the consequent replica-symmetry-broken distribution of the order parameter. Therefore, at any finite temperature the thermal fluctuations are unable to help the localized system to come out or escape from the macroscopically high free-energy barriers to reach the ground state (by flipping finite fraction of spins). With the aid of the transverse field the system can tunnel through such free-energy barriers (Das and Chakrabarti, 2008; Mukherjee and Chakrabarti, 2015; Ray et al., 1989). As a consequence, at low temperatures, the phase transition is governed by the quantum fluctuation and the system essentially exhibits quantum critical behavior (see the discussion on “possible restoration of ergodicity through quantum tunneling” for appropriate parameter space in the quantum SK model (Leschke et al., 2021)).

Study on the nature of the order parameter distribution in the spin glass phase at finite temperatures through Monte Carlo simulations also showed (Mukherjee and Chakrabarti, 2019) that in the high-temperature (low-transverse-field) classical fluctuation dominated spin glass region, along with the peak at the most probable value of the order parameter, the distribution contains a long tail (extending up to the zero value of the order parameter). This tail did not vanish even in the large system size limit, which indicated that the order parameter distribution remains Parisi type (replica Symmetry broken), corresponding to the nonergodic region SG(NE) (Fig. 5A) of the spin glass phase. On the other hand, in the low temperature (large transverse field) region, where the order parameter distribution effectively converges to a Gaussian form (with a peak around the most probable value) in the infinite-system-size limit. This indicates the existence of a single (replica-symmetric) order parameter in this ergodic region SG(E) of the spin glass phase. At zero temperature, the extrapolated order parameter distribution function showed a clear tendency to become one with a sharp peak (around the most probable value) in the large-system-size limit, suggesting the conclusion that the ergodic and non-ergodic regions of the spin glass phase are separated by a line possibly originating from point ($T = 0, \Gamma = 0$) and extending up to the quantum-classical crossover point (T near 0.49 and Γ near 1.31) on the phase boundary (see Fig. 5A). In order to find the role of such quantum-fluctuation-induced ergodicity in the (annealing) dynamics, they studied the variation of the annealing time τ (required to reach close to the ground state(s)) with the system size following the schedules $T(t) = T_0(1-t/\tau)$ and $\Gamma(t) = \Gamma_0(1-t/\tau)$. Attempts were made to reach a desired preassigned very low energy state (near the ground state) at the end of the annealing dynamics (in time τ), keeping both T and Γ nonzero (but very small) at the end of the annealing schedule as the Suzuki-Trotter Hamiltonian (which governed the annealing dynamics) has singularities at both $T = 0$ and $\Gamma = 0$ (starting with T_0 and Γ_0 corresponding to the paramagnetic region of the phase diagram). They found (see Fig. 5B) that the average annealing time does not depend on the system size when annealing is carried out along paths that pass entirely through the ergodic region, whereas the annealing time becomes much larger and strongly size-dependent for paths that pass through the nonergodic region of the spin glass phase. These confirm the earlier observations (Mukherjee and Chakrabarti, 2015; Ray et al., 1989) regarding the annealing time behavior, occurring due to tunneling through macroscopically tall but thin free-energy barriers in the SK model. In fact, the temporal variations of the average spin autocorrelation at finite temperatures also showed distinct behavior in these two regions of the spin glass phase of the quantum SK model. While at high temperatures, in the classical fluctuation dominated (nonergodic)

Fig. 5 (A) Schematic phase diagram of the quantum SK model. The spin glass and paramagnetic phases are denoted by SG and PM, respectively. Numerical results showed (Mukherjee and Chakrabarti, 2019) that the spin glass phase is further divided into two regions: ergodic spin glass phase SG(E) and nonergodic spin glass phase SG(NE). The quantum-classical crossover point in the critical behavior of the model is indicated by the red dot on the SG-PM phase boundary. The annealing behavior for the schedules $T(t) = T_0(1 - t/\tau)$ and $\Gamma(t) = \Gamma_0(1 - t/\tau)$, with T_0 and Γ_0 values corresponding to the paramagnetic phase are shown in (B). The Variation of annealing time τ with S , the length of the arc measured along the phase boundary (starting from the zero-temperature quantum transition point) to the intersection of the annealing line with the phase boundary. Low values of S correspond to the SG(E)-PM phase boundary, while higher values of S correspond to SG(NE)-PM boundary. The annealing time τ is clearly system size independent when the annealing path passes through the SG(E) region and increases rapidly with the system size when it pass through the SG(NE) region. From Mukherjee S and Chakrabarti BK (2019) On the question of ergodicity in quantum spin glass phase and its role in quantum annealing. *Journal of the Physical Society of Japan* 88: 061004.

region of the spin glass phase (SG(NE) region in Fig. 5A), one obtains very large values of the fitting relaxation times, the fitting relaxation times become order of magnitude smaller in the low temperature quantum fluctuation dominated region (SG(E) in Fig. 5A) presumably because of quantum tunneling (Mukherjee and Chakrabarti, 2019). These investigations clearly indicated the existence of a high-temperature (low-transverse-field) nonergodic region as well as a low-temperature (high-transverse-field) ergodic region in the spin glass phase. The line separating these two regions starts from $T = 0$, $\Gamma = 0$ and intersects the spin glass phase boundary at the quantum-classical crossover point (see Fig. 5A). The annealing behaviors are indicated in Fig. 5B, showing that the annealing time τ is practically independent of N when the annealing schedule (line) passes through the ergodic spin glass region (at low T and high Γ).

Quantum annealer using optical lattice in a cavity

Indeed, Starchl and Ritsch (2022) studied a minimal Bose-Hubbard type system containing two atoms inside a cavity-generated optical lattice induced by an external trapping potential and directly pumped by two laser beams resulting in photon scattering into two separate cavity modes. Introduction of an additional local energy shift for a specific lattice site allows creating a unique energy separated optimal ground state for the problem Hamiltonian. The main focus was to compare the full quantum mechanical model with the semi-classical model, where the field mode induced interactions are approximated by classical coherent fields. The investigation revealed strong differences between the quantum and semi-classical model, which can be cast into a sort of phase diagram separating a distinct parameter region where (partial) quantum annealing does not find the optimum in the semi-classical approach, while full quantum annealing does. They found strong evidence for the involvement of entanglement in two ways. First, Starchl and Ritsch (2022) confirmed the importance of vanishing entanglement at the end of the protocol and its influence on the minimal time needed for a successful simulation. Second, they identified a novel role of the maximum entanglement generated during the quantum annealing protocol in finding an optimal solution to the problem. They also studied the impact of different photon number cut-offs in the numerical quantum simulation. Most surprisingly they found improvement in the optimization success rate even for short simulation times when they used too low cut-off numbers to get a numerically accurate solution of the

Fig. 6 (A) Color density plot showing the solution fidelity after an adiabatic sweep using a Hamiltonian description with a classical mean-field approximation of the photon cavity modes. The parameter U describes the particle-particle on-site repulsive interaction and the parameter V represents the total potential depth of the specifically shifted lattice site, to create an impurity with a unique optimal solution. Three regions are clearly visible, a green-yellowish one, where the correct solution of two-particle on the mentioned lattice site is found, a bluish region with finite overlap but non-optimal solution, and a dark purple region with minimal overlap to the optimal solution. (B) Color density plot for the same parameter range showing the maximum entropy generated during the adiabatic sweep. In comparison, a connection between low maximum entropy and high success probability can be seen. Courtesy, Starchl E and Ritsch H (2022) Unraveling the origin of higher success probabilities in quantum annealing versus semi-classical annealing. *Journal of Physics B: Atomic, Molecular and Optical Physics* 55: 025501; private communication.

Schrödinger equation. Using higher cut-off numbers and thus a better representation of the exact quantum dynamics seems to be more relevant only for longer simulation times with very high success rates (see Fig. 6). These observations indicate a clear quantitative improvement of the annealing process for a full quantum system compared to a semi-classical one.

Conclusion and further reading

Quantum Annealing is now a very well developed subject, both theoretically as well as experimentally (see e.g., Brooke et al. (1999); Das and Chakrabarti (2008)). The breakthrough implementation of quantum annealing, employing superconducting qubits in successive generations of the D-wave annealers (Johnson et al., 2011) since 2011 and their availability in the market, has helped the growth of analog quantum computing in a major way. In fact, the availability of commercial quantum annealing condensed matter devices (like the D-wave systems) have revolutionized quantum information processing and computing algorithms for optimization across many disciplines, and led to developments which were unthinkable about a decade back. We would refer the readers to a few recent studies to get further information and ideas. For discussions on quantum versus classical annealing the readers may consult Heim et al. (2015), while for discussions on the efficiency of quantum versus classical annealing in the context of learning problems, the readers may consult Baldassia and Zecchinaa (2018) (see Nath et al. (2021) for a recent review on machine learning using quantum annealing). For a discussion on fault-tolerant quantum heuristics in the context of combinatorial optimizations,

one may consult Sanders et al. (2020), and Pelofske et al. (2022) for the indication of a major success using parallel quantum annealing algorithms. For a discussion on computer aided design of heterogeneous materials using quantum annealing algorithms, one may consult (Sahimi and Tahmasebi, 2021). For recent extensive discussions on both theoretical and experimental developments, the readers are referred to the books (Dutta et al., 2015; Tanaka et al., 2017) and reviews (Albash and Lidar, 2018; Hauke et al., 2020).

Acknowledgments

Abstract

Molecular dynamics calculations have been an essential tool to model the structural and dynamic properties of atomic systems. Apart from providing the experimental tool set for statistical mechanics, molecular dynamics simulations are routinely used to understand, interpret and predict microscopic processes in realistic materials. Machine learning techniques have helped to accelerate molecular dynamics in several ways: surrogate models, trajectory analysis, enhanced sampling, to name a few. This entry focusses largely on machine learning interatomic potentials (MLIPs), presenting their development grounded on ab initio methods and analytical potentials. The basic ingredients of the methodology is discussed through examples, and some concrete implementations are mentioned. Applications highlighting the new possibilities offered by MLIPs are shown, as well as some remarks on future directions.

Introduction

Molecular dynamics (MD) is a numerical technique used to simulate the motion of interacting atomic particles as well as to generate statistical ensembles of atomic configurations (Frenkel and Smit, 2002). While the motion of atomic particles cannot be obtained in an analytic form, except for the simplest cases, well established numerical integration techniques are routinely used to generate high resolution, arbitrarily long trajectories. The fundamental challenge of the field is the drive to increase the accuracy of the trajectory, inasmuch as to make simulations more realistic and predictive.

The key quantity that determines the quality of each integration step during a MD calculation is the interaction energy model between the particles. Traditionally, interactions have been approximated by simple analytical forms based on theoretical considerations, also known as force fields, and parameterized using experimental data or a few reference quantum mechanical calculations. With the development of quantum mechanical calculations, it has become feasible to evaluate atomic forces from solving the Schrödinger equation, and use these to propagate the atomic trajectories (Car and Parrinello, 1985; Payne et al., 1992). Termed ab initio molecular dynamics (AIMD), the technique is regarded as truly predictive (Brommer et al., 1992) within the approximations employed in the numerical solution of the quantum mechanical equations. This is in contrast to MD based on traditional or empirical force fields, which are generally used to interpret experimental phenomena or study generic statistical mechanics processes.

Very simplistically, the main limitation of AIMD is the lack of access to large time and length scales, due to the computational complexity and unfavorable scaling of ab initio methods, while empirical force fields lack accuracy and therefore predictive capability, because their simplified form remains only locally valid (Stillinger and Weber, 1985).

[☆]Change History: March 2023. AP Bartók updated the chapter.

It is useful to consider the reason empirical potentials have been typically formulated using simple analytical expressions with few free parameters. In the absence of reliable quantum mechanical data, only a few experimental data points have been available to find numerical values for the potential parameters, such as thermal data, elastic and vibrational properties or defect energies (Tersoff, 1988). Therefore, traditional potentials rely on the theoretical considerations encapsulated in the functional form.

Algorithmic developments (Becke, 2014), aided by a massive increase in computational power have made it possible to generate a large number of reliable reference data points using ab initio methods. This has largely coincided with an explosion in non-linear, non-parametric regression techniques, termed as machine learning (ML) (Mackay, 2003), allowing to define significantly more flexible functional form for atomic interactions, which can be fitted using reference ab initio data.

Even though MLIPs are typically slower to evaluate computationally than empirical force fields due to their more complex functional form, they remain linear scaling with system size and significantly faster than ab initio methods, while approaching ab initio accuracy in the fitting domain (Zuo et al., 2020). Another favorable feature of MLIPs is that they are extensible, inasmuch as their flexibility allows increasing their domain of validity by adding more reference data (Vandermause et al., 2020; Gubaev et al., 2019).

Apart from surrogate models for atomic interactions, ML techniques have found application in analyzing MD trajectories (Cheng et al., 2020) as well as aiding enhanced sampling techniques (Bonati et al., 2019). Regardless of the model representing the atomic interactions, analysis of the resulting trajectories benefits from unsupervised ML methods to discover patterns and processes.

In the following sections, I will review machine learning interatomic potentials, focusing on general concepts as well as practical implementations and highlighting a few applications. I will also discuss other uses of ML techniques in MD simulations and provide an outlook of the state-of-the-art and future challenges.

Molecular dynamics calculations

Molecular dynamics

In its simplest form, MD is based on Newtonian mechanics, solving the second order differential equations describing Newton's law of motion

$$m_i \ddot{\mathbf{r}}_i = \mathbf{F}_i \equiv -\nabla_{\mathbf{r}_i} E, \quad (1)$$

where m_i and $\mathbf{r}_i$ represent the mass and position of atom i , respectively, and E describes the potential energy of all the N interacting particles. The force acting on atom i , $\mathbf{F}_i$ is obtained as the negative gradient of the potential energy.

The underlying assumption is that atoms can be regarded as classical particles, ignoring their quantum nature, which is well justified in case of heavier nuclei (Marx and Parrinello, 1996). Lighter nuclei may require quantum mechanical treatment, some of which are also based on MD, such as the Path Integral Molecular Dynamics method, which are out of the scope of this entry, but MLIPs remain equally applicable.

Typical solutions of (1) are based on numerical integration schemes, which propagate the trajectory in discrete time steps Δt , collecting a time series of positions and velocities. Most often used are the Verlet or the closely related Velocity Verlet algorithms (Frenkel and Smit, 2002), which have advantages that they are stable, as errors in the integration are in the fourth order above; and the integration is time reversible, preserving this fundamental symmetry of Hamiltonian dynamics.

As the numerical integration is a well established technique, with a well controlled accuracy if the discretization time step is small enough, the quality of the trajectory is determined predominantly by the description of the atomic interactions. Also, for all but the simplest of models, the computational cost of a MD simulation is dominated by the evaluation of the atomic forces.

Potential energy surfaces

In our context, the interaction model is based on the Born-Oppenheimer approximation, applicable to problems where the degrees of freedom of the electrons and nuclei can be treated separately. The Born-Oppenheimer approximation assumes that the combined wave function of the electrons and nuclei Ψ , is separable in the form

$$\Psi(\mathbf{r}_{n,1}, \mathbf{r}_{n,2}, \dots; \mathbf{r}_{e,1}, \mathbf{r}_{e,2}, \dots) = \chi(\mathbf{r}_{n,1}, \mathbf{r}_{n,2}, \dots) \psi(\mathbf{r}_{e,1}, \mathbf{r}_{e,2}, \dots), \quad (2)$$

where $\mathbf{r}_{n,i}$ and $\mathbf{r}_{e,j}$ denote the Cartesian coordinates of the i -th nucleus and j -th electron, respectively. From this assumption follows that the electronic Schrödinger equation, with the electronic Hamiltonian $\hat{H}_e$ parameterized by the coordinates of the nuclei, can be solved separately as

$$\hat{H}_e(\mathbf{r}_{n,1}, \mathbf{r}_{n,2}, \dots) \psi = E(\mathbf{r}_{n,1}, \mathbf{r}_{n,2}, \dots) \psi, \quad (3)$$

resulting in a potential energy surface (PES) function which depends only on the coordinates of the nuclei, also known as the Born-Oppenheimer surface.

As the potential energy E is assumed to depend on the coordinates of the nuclei, the electronic degrees of freedom need not be explicitly considered, and the solution of (3) is often regarded as a black-box calculation.

A large proportion of atomic modelling problems can be characterized by the ground state wavefunction and therefore the Born-Oppenheimer approximation provides an accurate solution, therefore for the remainder of this entry I focus on the MD of classical particles interacting via a surrogate model of the Born-Oppenheimer surface.

Surrogate models

It is evident from the Born-Oppenheimer approximation that in case of an AIMD simulation, the particulars of the electronic structure are irrelevant, and only the forces based on the PES are used from the solution of the electronic Schrödinger equation to propagate the trajectory. The use of surrogate models for the PES, which bypass the explicit solution of the Schrödinger equation is therefore straightforward and widely used (Deringer et al., 2021).

For an isolated system with relatively few degrees of freedom, such as a small molecule, it is possible to create PES models that explicitly contain all atomic coordinates. Examples include models for H_3^+ (Adamowicz and Pavanello, 2012), H_2O (Partridge and Schwenke, 1997) or CH_5^+ (Thompson et al., 2005). In isolated systems, symmetrized coordinates describing the entire entity are used to form basis functions, which are often physically motivated, and a fitting procedure to reference data is used to determine the parameters of basis functions and corresponding coefficients.

As an example, let us consider the model for describing the PES of the water molecule developed by Partridge and Schwenke (1997). A convenient representation of the geometry of the water molecule is provided by the length of the two O—H bonds (r_1, r_2) and the bond angle θ . As opposed to the representation given by the 9 Cartesian coordinates, the representation by bond lengths and angle eliminates the translational and rotational degrees of freedom, to which the PES is invariant, therefore these invariant features are built in when formulating E as a function $E(r_1, r_2, \theta)$. Partridge and Schwenke suggested the form

$$E(r_1, r_2, \theta) = E_a(r_1) + E_a(r_2) + E_b(r_{\text{HH}}) + E_c(r_1, r_2, \theta) \quad (4)$$

where E_a takes the form of the Morse potential

$$E_a(r) = D\{\exp[-2a(r-r_0)] - 2\exp[-a(r-r_0)]\}, \quad (5)$$

E_b is a simple repulsive term given by

$$E_b(r) = A \exp(-br), \quad (6)$$

and the three-body term E_c is

$$E_c(r_1, r_2, \theta) = c_{000} + \exp[-\beta(r_1-r_e)^2] \exp[-\beta(r_2-r_e)^2] \\ \times \sum_{ijk} c_{ijk} \left(\frac{r_1-r_e}{r_e}\right)^i \left(\frac{r_2-r_e}{r_e}\right)^j [\cos\theta - \cos\theta_e]^k. \quad (7)$$

The three-body component includes 245 terms, and coefficients were fitted using a least squares algorithm that minimized the difference between the model PES and 771 ab initio energies calculated at different geometries. It is remarkable that even though there is no reference to ML, the functional form is equivalent to those used in MLIPs, as we shall see later.

Extended systems pose a different challenge. As the formal definition of the PES function depends on $3N$ Cartesian coordinates, with varying number of atoms the number of arguments of E changes, therefore a rigid functional form would be very restricted. While according to (2) the energy is an N -body quantity, the principle of nearsightedness of electronic matter proposed by Prodan and Kohn, 2005 suggests that there exists a locality which can be exploited to approximate the full N -body interaction energy by simpler terms.

A common approach to decompose the total energy into more manageable terms is to apply the many-body expansion (MBE) (Richard et al., 2014), where

$$E(r_1, r_2, \dots, r_N) = \sum_i E_i^{(1)} + \sum_{i<j} E_{ij}^{(2)} + \sum_{i<j<k} E_{ijk}^{(3)} + \dots \quad (8)$$

and we assume that (i) the expansion may be truncated at reasonably low orders; (ii) the individual terms are local, i.e. they tend to zero as pairwise distances increase. The MBE reduces the complexity by substituting a $3N$ -dimensional function by functions of significantly lower, and constant, dimensionality as well as limiting the domain of each term by the locality assumption. It is important to note that long range interactions, such as dispersion or the Coulomb interaction, form an exception as truncation may lead to the omission of important physical effects, but there exists well-established methods to approximate these contributions to the total energy and only consider the local contributions within the MBE approximation.

Examples for models based on the MBE in condensed systems include the ubiquitous Lennard-Jones potential (Jones, 1924) for noble gases and the Stillinger-Weber potential (Stillinger and Weber, 1985) for silicon. The Lennard-Jones potential is based on truncation at the two-body term

$$E = \sum_{i<j} 4\epsilon \left(\frac{\sigma_{ij}^{12}}{r_{ij}^{12}} - \frac{\sigma_{ij}^6}{r_{ij}^6} \right). \quad (9)$$

Indeed, Cao and Berne (1992) found that including many-body effects is quantitatively significant, although the qualitative structural features of noble gas clusters and liquid remain unchanged, justifying the truncation as an approximate model for interactions of noble gas atoms.

The Stillinger-Weber potential has the form of

$$E = \sum_{i < j} A \left(B r_{ij}^{-p} - r_{ij}^{-q} \right) \exp \left[\left(r_{ij} - a \right)^{-1} \right] + \sum_{i < j < k} \lambda \exp \left[\gamma \left(r_{ij} - a \right)^{-1} + \gamma \left(r_{ik} - a \right)^{-1} \right] \left(\cos \theta_{ijk} + \frac{1}{3} \right)^2, \quad (10)$$

illustrating a truncation at the three-body term. Inspecting its functional form, it becomes apparent that the three-body term favors a tetrahedral arrangement, which is appropriate for the diamond phase, but unphysically destabilizes other, high-pressure phases, such as the β -tin or simple hexagonal phases (Pizzagalli et al., 2013). Other parameterizations or functional forms may remedy this particular failure, nevertheless the Stillinger-Weber potential illustrates the major limitation of the less flexible forms of traditional interatomic potentials.

Another ansatz for the total energy was obtained by Daw and Baskes (1983) and later by Finnis and Sinclair (1984) by considering a series of approximations to Density Functional Theory (DFT). Daw and Baskes (1983) wrote the total energy as

$$E(r_1, r_2, \dots, r_N) = \sum_i^N E^{(n)}(\rho_i) + \sum_{i < j} E^{(2)}(r_{ij}), \quad (11)$$

where $E^{(n)}$ is an n -body term interpreted as the density dependent energy functional, where ρ_i is the local electron density at atom i and $E^{(2)}$ is a pair term. The electron density is approximated as a sum of static terms contributed by nearby atoms

$$\rho_i = \sum_j \rho(r_{ij}), \quad (12)$$

hence the n -body term is local. Finnis and Sinclair (1984) provided a connection with tight-binding theory.

Machine learned interatomic potentials

While the accuracy and transferability of AIMD, within the approximations employed in the underlying ab initio method, is unquestionable, it is clear that AIMD is limited in accessing time and length scales necessary to study certain phenomena. Slow processes require the collection of long trajectories, which have a correspondingly large computational cost. Plane-wave DFT (Martin, 2004), the most widely used ab initio method for MD scales cubically with system size, meaning that large systems that are necessary to minimize finite size effects quickly become out of reach, limiting system sizes to a few hundreds of atoms. Even linear-scaling DFT implementations have such a large prefactor that it is not practical to sample long MD trajectories.

Surrogate models, as introduced previously, offer a major increase in speed and a favorable linear scaling with system size due to the locality assumption.¹ A natural development is the use of flexible functional forms for the terms in the MBE represented by (8) or (11), which is enabled by regression techniques based on ML.

Representations

The first ingredient to realize a ML based force field model is to define representations that map Cartesian coordinates of atoms onto features that are invariant to basic symmetry operations, much in the spirit of the Partridge-Schwenke water model described in Section “Surrogate models”. Such representations form the input variables of subsequent regression methods approximating the individual terms in the total energy expression. As the total energy of a system is invariant to rotations, translations, reflections and permutations of the indices of the same atomic species, it is convenient to build in these symmetries into the transformation that maps Cartesian coordinates, which do not obey these symmetries, onto invariant features or descriptors.

Further desirable properties of the transformation include smoothness, since the Born-Oppenheimer PES in most cases is a continuous and differentiable function of atomic coordinates – which is itself an necessary condition for most integrators used in MD simulations. For example, the representation formed by ordered list of interatomic distances may have the necessary invariances, but discontinuities in the Jacobian are introduced, meaning the forces derived from a model based on this representation would be discontinuous (Musil et al., 2021). However, descriptors can be constructed by choosing appropriate combinations of pair-wise distances, such as those provided by a suitably constructed neural network (Schütt et al., 2018).

The locality assumption can also be implemented at the level of the descriptors. If a descriptor is attributed to an atom, a cutoff function can limit its dependence to the neighboring atoms within a certain distance.

¹We note that there exist efficient algorithms to evaluate long range interactions, for example by Essmann et al. (1995).

Fig. 1 The family tree of descriptors, with equivalencies noted. Reproduced from Musil F, Grisafi A, Bartók AP, Ortner C, Csányi G, and Ceriotti M (2021) Physics-inspired structural representations for molecules and materials. *Chemical Reviews* 121(16):9759–9815. doi: 10.1021/acs.chemrev.1c00021. <http://eutils.ncbi.nlm.nih.gov/entrez/eutils/efetch.fcgi?dbfrom=pubmed&id=34310133&retmode=ref&cmd=prlinks>, licensed under the CC-BY 4.0 License.

A large number of representations have been suggested, some of which are illustrated on Fig. 1. Particularly successful have been representations based on atomic densities. The atomic environment of atom i in an extended structure is characterized by the density field

$$\rho_i(\mathbf{r}) = \sum_j f_{\text{cut}}(r_{ij}) g(\mathbf{r} - \mathbf{r}_{ij}), \quad (13)$$

where f_{cut} is a suitably chosen cutoff function that enforces locality, allowing neighboring atoms to enter and exit the cutoff radius in a smooth fashion; g may be a function with compact support, such as the Dirac-delta or a Gaussian function. Neighbor density representations implement invariance to permutations due to the commutativity of the summation, invariance to translations as positions are relative to the central atom as well as locality by using the cutoff function. Invariance to rotations and reflections may be achieved by first considering a basis set expansion using spherical harmonics Y_{lm} and radial basis functions b_n as

$$\rho_i(\mathbf{r}) = \sum_{nlm} c_{nlm}^i Y_{lm}(\hat{\mathbf{r}}) b_n(\mathbf{r}). \quad (14)$$

The power spectrum components are formed from the coefficients as

$$\mathbf{p}_{nn'l}^i \equiv \sum_{m=-l}^l c_{nlm}^{i*} c_{n'l m}^i \quad (15)$$

are invariant to rotations and reflections, and may be regarded as a basis set expansion of the histogram of three-body terms within the atomic neighborhood environment (Bartók et al., 2013). It is also possible to generate higher order correlations representing four- or more body terms, such as the bispectrum (Bartók et al., 2013; Drautz, 2019). Arbitrarily high body order correlations can be encoded in the Moment Tensors (Shapeev, 2016) and the Atomic Cluster Expansion framework (Drautz, 2019).

A related family of descriptors has been suggested by Behler and Parrinello, 2007, such as

$$G_{i,n}^{\text{radial}} = \sum_j \exp \left[-\eta_n (r_{ij} - r_n)^2 \right] f_{\text{cut}}(r_{ij}) \quad \text{and} \quad (16)$$

$$G_{i,n}^{\text{angular}} = 2^{1-\zeta_n} \sum_{jk} (1 + \lambda_n \cos \theta_{ijk})^{\zeta_n} \exp \left[-\eta_n (r_{ij}^2 + r_{ik}^2) \right] f_{\text{cut}}(r_{ij}) f_{\text{cut}}(r_{ik}). \quad (17)$$

By constructing a set of these functions based on different η_n , r_n , ζ_n and λ_n values, a representation up to three-body correlations is obtained. It is clear from the construction of the Behler-Parrinello (BP) descriptors that they possess all the desirable invariant properties. It has also been shown (Musil et al., 2021) that the terms in the BP descriptors are equivalent, up to a basis transformation, to terms in the power spectrum in Eq. (15).

It is important to note, however, that important features of the atomic neighbor environment are omitted from descriptors based on up to three-body correlations, meaning that it is possible to construct two different atomic neighborhood environments, which are not related by rigid body symmetries, that have the same power spectrum of BP descriptors (Pozdnyakov et al., 2020). Conceivably, this shortcoming can lead to inaccurate surrogate models, as two identical representations can only map to equal energy terms. Descriptors encoding higher body correlations, such as ACE (Drautz, 2019), MTP (Shapeev, 2016), SNAP (Thompson et al., 2015) remedy this incompleteness of the representation.

Regression

The key innovation brought by ML to the field of interatomic potential development is the introduction of non-linear regression techniques and robust fitting methodologies. Each term in the MBE expression can be approximated by a high-dimensional function that depends on a descriptor, such as those illustrated in the previous section, allowing the use of arbitrarily high body-order expansion. Denoting a many-body energy function associated with an atomic site by ε parameterized by $\mathbf{w}$, the total energy of an N -atom system is expressed as

$$E = \sum_i^N \varepsilon(\mathbf{d}_i; \mathbf{w}), \quad (18)$$

where I ignored long-range contributions and used a generic descriptor vector $\mathbf{d}$ for each atom. Given a suitable database of reference ab initio data, consisting of total energies (E_I), forces etc. associated with atomic configurations, the regression problem can be formulated as the least square problem

$$\mathcal{L}_E = \sum_I \left[E_I - \sum_{i \in I} \varepsilon(\mathbf{d}_i; \mathbf{w}) \right]^2 \quad (19)$$

with analogous expressions for other microscopic ab initio quantities. Minimizing $\mathcal{L}$ with respect to $\mathbf{w}$ results in a surrogate model that interpolates between the reference data points, and thanks to the highly flexible functional form (c.f. high number of parameters in $\mathbf{w}$) is extensible when new points are added to the database.

Some descriptors presented in Section “Representations” provide a highly non-linear mapping, and as a consequence successful interatomic potential were obtained by simple linear regression, such as Moment Tensor Potentials (Shapeev, 2016), the Spectral Neighbor Analysis Potentials (Thompson et al., 2015) and ACE potentials (Drautz, 2019).

MLIPs based on other descriptors benefit from non-linear regression, such as Gaussian Process Regression (GPR) or artificial neural networks. GPR, schematically represented in Fig. 2, is a kernel method, and prediction of $\tilde{y}$ at an arbitrary input point $\mathbf{d}$ can be expressed as

$$\tilde{y}(\mathbf{d}) = \sum_{m=1}^M w_m k(\mathbf{d}, \mathbf{d}_m), \quad (20)$$

where M is a set of representative points and k is a kernel function, responsible for defining a similarity between two data points. A key ingredient in fitting the weights $\mathbf{w}$ is the use of regularization, formulated as an additional penalty term in the least squares problem

Fig. 2 Left panel (A): schematic of GPR. Right panel (B): a simple, fully connected neural network architecture. Figure (A) reproduced from Deringer VL, Bartók AP, Bernstein N, Wilkins DM, Ceriotti M, and Csányi G (2021) Gaussian process regression for materials and molecules. *Chemical Reviews* 121(16):10073–10141. doi: 10.1021/acs.chemrev.1c00022. <http://eutils.ncbi.nlm.nih.gov/entrez/eutils/elink.fcgi?dbfrom=pubmed&id=34398616&retmode=ref&cmd=prlinks>, licensed under the CC-BY 4.0 License. Figure (B) reprinted with permission from Behler J (2021) Four generations of high-dimensional neural network potentials. *Chemical Reviews* 121(16):10037–10072. ISSN 0009-2665. doi: 10.1021/acs.chemrev.0c00868. Copyright 2021 American Chemical Society.

$$R = \sum_{m,m'} w_m k(\mathbf{d}_m, \mathbf{d}_{m'}) w_{m'} \quad (21)$$

that is responsible for avoiding overfitting (Mackay, 2003). Non-linearity is introduced by the kernel function, also allowing the coupling of different descriptor elements, thereby increasing the effective body-order of the energy term, although not eliminating completely the issues caused by the incompleteness of descriptors (Pozdnyakov et al., 2020). Successful MLIP frameworks based on GPR include the Gaussian Approximation Potentials (GAP) (Bartók et al., 2010), symmetric Gradient Domain Machine Learning (sGDML) (Chmiela et al., 2019), or the interpolation scheme based on reproducing kernel Hilbert space by Koner and Meuwly (2020).

An alternative method that has been widely adopted is the regression technique based on artificial neural networks (ANNs). In this context, the mathematical form of ANNs is described by layers, where $\mathbf{y}^k$ is the vector describing the k -th layer. Each layer is obtained from the previous one according to the formula

$$y_i^{k+1} = f \left(b_i^k + \sum_j^{n_k} W_{ij}^k y_j^k \right) \quad (22)$$

where $\mathbf{b}^k$ and $\mathbf{W}^k$ are free parameters called bias and weight, respectively; and f is the *activation* function (Mackay, 2003). Recursive evaluation of (22) with the descriptor vectors as the input layer $\mathbf{y}^0$ and the local energy terms ε as the output layer defines the functional form of the MLIP. A sketch of a simple ANN on Fig. 2 illustrates the interconnected nature of this construction. Similarly to kernel methods, a non-linear activation function f is responsible for mixing information from different descriptor elements, allowing the representation of higher body interactions. The fitting is performed by minimizing the difference between the predicted and ab initio reference properties with respect to the free parameters, a process which has been considerably streamlined in the last two decades (Nielsen, 2015).

Many MLIP frameworks are based on ANNs, for example the neural network potentials originally developed by Behler and Parrinello (Behler and Parrinello, 2007; Behler, 2021), SchNet (Schütt et al., 2018), SpookyNet (Unke et al., 2021), ANI (Smith et al., 2017), DeepMD (Zhang et al., 2018) or PhysNet (Unke and Meuwly, 2019) among others.

Data generation

A significant aspect of fitting MLIPs is generating the ab initio reference database. Unlike other applications in ML which operate with a fixed *training* data set, we can relatively easily choose data points and expand the original data set as required. Even the seminal work of Behler and Parrinello used an iterative approach to train a neural network potential, starting with an MLIP fitted on a data set obtained from configurations collected using ab initio MD. Performing subsequent MD, Monte Carlo and metadynamics (Laio and Parrinello, 2002) calculations using MLIPs, new configurations were added to the training set, and this procedure was repeated until a desired accuracy was achieved.

The problem of iterative database generation highlights the interpolative nature of MLIPs, as predictions that are concerning atomic environments outside of the fitting domain are uncontrolled. While most approaches suggest uncertainty quantification, which can be based on Bayesian error prediction available for GPR or ensemble techniques which are applicable to any fitting method, the primary aim is ascertain a ML model that is reliable across phases and includes defects, surfaces or any structural feature of interest. An attempt to generate a general MLIP for silicon was presented by Bartók et al. (2018), which necessitated a carefully assembled database that covered multiple crystalline, liquid and amorphous phases; surfaces; defects; as well as high-energy, unrealistic configurations which serve to avoid the ML model predicting unphysically low energy to “unseen” configurations. While useful to demonstrate the possibilities and potential accuracy of the MLIPs, it is clear that more automated protocols are required to reliably generate reference databases.

Later approaches include performing quenches from high-temperature liquid to amorphous states in an iterative fashion, bootstrapping from a direct ab initio simulation, and continuing with MLIPs, adding configurations to the reference database if the accuracy of the ML property prediction compared to ab initio is above a predefined threshold (Deringer and Csányi, 2017). A similar iterative process, based on random structure search was suggested by Bernstein et al. (2019).

Active learning, where feedback from uncertainty quantification is used to select new training configurations offer a further step of automation was suggested by Gubaev et al. (2019), Jinnouchi et al. (2019), Smith et al. (2018), and Vandermause et al. (2020). In these frameworks a seamless switching between MD driven by a MLIP and ab initio calculations is realized that automatically computes new reference points and refits the MLIP as required.

Applications

With MLIPs being established as direct substitutes of ab initio MD simulations, the list of applications cannot be complete, so I will only focus on a few examples, which illustrate problems where ab initio accuracy was needed, but had been impractical before surrogate models based on ML were developed.

Fig. 3 Experimental (grey area) and simulated (DFT and MLIP, blue and red lines, respectively) IR spectrum of methanol. Figure reproduced from Gastegger M, Behler J, and Marquetand P (2017) Machine learning molecular dynamics for the simulation of infrared spectra. *Chemical Science* 8(10): 6924–6935. ISSN 2041-6520. doi: 10.1039/c7sc02267k, licensed under the CC-BY 4.0 License.

Organic molecules

A high-dimensional neural network potential was fitted by Gastegger et al. (2017) to model organic molecules, including the charge distribution. The Fourier transform of the dipole moment autocorrelation function, obtained from MD simulations, is proportional to the infrared (IR) spectrum. Gastegger et al. have shown that the results calculated from MLIP trajectories not only match those from ab initio simulations, but fit experiments very closely, as shown in Fig. 3.

While for such a small molecule as methane a benchmark calculation comparing the MLIP model to the reference ab initio method is feasible, it follows naturally that much larger systems are only available to model using the MLIP.

Water

Water has an exceptionally complex phase diagram, which has been a long-standing challenge to reproduce by computer simulations. Extensive sampling is required to map out the phase stability lines, which is impractical by ab initio MD due to the computational expense of such calculations. On the other hand, phase diagrams predicted using traditional interatomic potentials for water, such as the TIP4P/Ice model, are found to be inaccurate, especially at high pressures (Bore et al., 2022). Zhang et al. (2021) fitted a highly accurate Deep Potential model for water to construct a phase diagram with ab initio accuracy, which approximates the experimental phase diagram significantly closer, in a much broader range. Apart from validating the MLIP, the excellent agreement between the simulated and experimental phase diagrams highlight the accuracy of the reference DFT method, at an affordable computational cost.

Amorphous silicon

Determining realistic structural models of amorphous materials on the atomic level is challenging as characterization techniques lack the resolution to resolve the atomistic details of disordered structures. Simulations mimicking the experimental conditions at which amorphous compounds form require long time scales, which are required to model experimentally achievable cooling rates.

To model disorder on a sufficiently large length scale, large system sizes are needed. Direct ab initio simulations are out of reach, but ab initio may be required to generate realistic structural models that reproduce experimental observations. Deringer et al. (2020) showed that traditional interatomic potentials suggested for silicon are inadequate to model the liquid-amorphous transition. The authors used the GAP silicon model by Bartók et al. to model the formation of amorphous silicon in simulation cells containing 100,000 atoms at a cooling rate of 10^{11} Ks⁻¹. Pressurization simulations of the amorphous silicon structures further revealed the previously unknown mechanism of crystallization through a very high density amorphous phase.

Further use of machine learning in molecular dynamics

In addition to generating trajectories in a reliable and predictive fashion, ML tools assist studies based on MD in several ways. Firstly, often a vast amount of data is generated, which needs to be analyzed and interpreted. In addition to quantities traditionally used to characterize atomic configurations, such as radial and angular distribution functions or bond order parameters (Steinhardt et al., 1983), descriptors combined with unsupervised learning techniques can be applied. Dimensionality reduction techniques help visualization and classification of atomic configurations or atomic neighborhood environments (Cheng et al., 2020; Shires and

Pickard, 2021). Closely related, ML techniques can be used to discover patterns, for example Bonati et al. (2021) used deep learning to automatically find collective variables describing slow modes in MD simulations. By using enhanced sampling based on such collective variables, rare events can be modelled more efficiently. Noé et al. (2019) showed that ML may be used to bypass MD altogether in sampling configurations, by employing Boltzmann generators to create representative samples without running costly MD simulations. As an alternative to using Newton's laws of motion to propagate trajectories in time, Deeptime (Hoffmann et al., 2022) implements methods that predict the state of a system based on an earlier instance.

Conclusion

In this entry to the encyclopedia, I have provided a bird's-eye view of the state of using machine learning techniques to enhance molecular dynamics simulations. Given the dynamic nature of the field, my contribution cannot be regarded as complete, and the methods mentioned here are only intended as an illustration of the current state of the field. With pointers to more specific reviews and original publications, the reader should be able to orient themselves and get started.

Being very much an active area of research, I have largely omitted from the entry the current efforts to treat long-range interactions. I have not discussed efficiency, apart from contrasting the favorable linear scaling of MLIPs to the cubic scaling of plane-wave DFT and higher order of quantum chemistry approaches. There is a strong ongoing effort in the community to improve the speed of MLIPs without compromising the accuracy, which will enable even larger scale and hence more realistic simulations.

Like ML in general, ML applications for MD are under constant development, with the field expanding every day. However, the last two decades have shown the viability of MLIPs and other ML techniques used in simulations, which I hope I managed to convey in this entry.

Abstract

Materials Informatics is a research field in materials science and engineering that is based on data-driven methods. Materials informatics can accelerate materials research and help to gain a deeper understanding of materials. Machine learning is used to analyze materials data obtained by various computational or experimental means and to predict material properties.

Key points

- Machine-learning-aided computational screening for materials discovery
- Basic machine-learning techniques
- Machine-learning potential as a surrogate of first-principles calculations
- Bayesian optimization for efficiently exploring good candidates

Introduction

Over the past 100 years, numerous material data have been reported by researchers around the world. These data include atomic, molecular, and crystal structures, electronic states (density of states, band structure, etc.), and physical properties (optical, electrical, magnetic, mechanical, etc.). These literature data have been collected and various material databases were constructed. In addition, computer simulation methods, mainly first-principles electronic structure calculations, have been developed which makes it possible to create systematic computational data. The Materials Project, the Open Quantum Materials Database (OQMD), Automatic FLOW for Materials Discovery (AFLOW) and the Novel Materials Discovery (NOMAD) are among the well-known computational materials science databases.

These big data have enabled data-driven approaches in materials science. For example, high-throughput first-principles calculations for various crystal structures and chemical compositions are becoming a conventional tool to search for materials exhibiting desired properties. Machine learning is a powerful technique to accelerate this screening process. Another use of machine learning is to obtain useful information (e.g., controlling factors for material properties) from available data. Applications of machine learning are expanding into experimental measurement and synthesis.

Computational screening

First-principles calculations based on the density functional theory (DFT) are the standard method for quantitatively describing material properties. By inputting the chemical composition and initial structure, the optimized structure, total energy, band dispersion, density of states, and various other physical quantities (formation energy, bulk modulus, phonon dispersion, electrical conductivity, optical absorption spectrum, magnetic moment, dielectric function, etc.) can be calculated numerically. Since first-principles calculations are non-empirical methods, they can deal with not only existing materials but also hypothetical materials and predict their properties.

Advances in methodology, algorithms, and computer hardware have enabled exhaustive first-principles calculations for a wide variety of conditions. Typically, hundreds to tens of thousands of structural and chemical composition calculations can be

Fig. 1 Workflow of direct screening using first-principles calculation.

Fig. 2 Workflow of virtual screening using first-principles calculation and machine learning.

performed. By comparing the results of these calculations, the best material with the highest score for a given task can be found. This is called direct screening (Fig. 1). Direct screening has become a common method for material search since the beginning of the 2010s. For example, Nishijima et al. carried out direct screening of cathode materials for lithium-ion batteries (Nishijima et al., 2014). They performed first-principles calculations of thousands of materials for 630 compositions, based on the hypothesis that volume changes associated with lithium charging and discharging affect the cycle life, and proposed $\text{Li}(\text{Fe}_{1-x}\text{Zr}_x)(\text{P}_{1-2x}\text{Si}_{2x})\text{O}_4$. Experimental tests showed that the cycle life of the cell containing the proposed cathode outperforms the cell containing the standard cathode by a factor of 5.

While it is possible to perform first-principles calculations for more than a few thousand materials, the computational cost is high. Virtual screening speeds up screening by utilizing machine learning (Fig. 2). Suppose we have computational data $\{x^{(i)}, y^{(i)}\}$ ($i = 1, 2, \dots, N$), where $x^{(i)}$ is the i -th material, $y^{(i)}$ is its property and N is the number of the data. We construct a machine learning model $y = f(x)$ from the data. The model is then used to screen materials and select candidate materials. Screening by machine learning is much faster than direct screening but has limitations in prediction accuracy. Therefore, in the final stage of virtual screening, the properties of the narrowed-down candidate materials are calculated using first-principles calculations to validate the results.

Machine learning

There are several techniques in machine learning. Clustering divides given data into several groups (Fig. 3). Classification is another technique that divides data into groups. In classification, each group is pre-labeled. For example, classification into gases, liquids, and solids, or metals and insulators. In the case of clustering as shown in Fig. 3, on the other hand, we do not know what A, B, and C mean. Therefore, clustering is an unsupervised learning, while classification is classified as supervised learning.

Regression is a supervised learning technique that uses statistical methods to estimate the relationship between the independent variable (explanatory variable) and the dependent variable (objective variable). The former is the variable of interest, and the latter is the variable used to explain it. For example, suppose we are now interested in the property y of the material $x = (x_1, x_2, \dots, x_d)$. Here, x is a numerical representation of the material and is called descriptor in materials informatics. The objective of the regression is to find the relationship $y = f(x)$ (Fig. 4). Various regression methods exist, including linear regression, neural network, kernel method, random forest, and support vector regression. The simplest model is a linear model represented as follows,

Fig. 3 Example of clustering. Data (black circles) on a two-dimensional (x_1 – x_2) plane are divided into three groups, A, B and C.

Fig. 4 Regression is a technique for estimating the relationship between the independent variable x and the dependent variable y . Dots represent data points and the red curve is a regression curve.

$$y = w_0 + w_1x_1 + w_2x_2 + \dots + w_dx_d.$$

Here, the parameters $\mathbf{w} = (w_0, w_1, w_2, \dots, w_d)$ are determined so that the loss function,

$$L = \sum_{i=1}^N \left\{ y^{(i)} - f(\mathbf{x}^{(i)}) \right\}^2,$$

is minimized. (The term linear means linear with respect to the parameter $\mathbf{w}$. A linear model need not be linear with respect to the variable $\mathbf{x}$.)

One measure of the accuracy of a machine-learning model is the coefficient of determination R^2 , defined as

$$R^2 = 1 - \frac{\sum_{i=1}^N \{y^{(i)} - f(\mathbf{x}^{(i)})\}^2}{\sum_{i=1}^N \{y^{(i)} - \bar{y}\}^2},$$

where $\bar{y}$ is the average of $y^{(i)}$ with respect to i . The maximum value of R^2 is 1. The larger R^2 is, the better the data is reproduced.

If more parameters than the number of data are provided, the data can be reproduced perfectly. However, a model that perfectly fits data containing noise behaves in a complex manner and does not have high predictive power for $\mathbf{x}$ not included in the data. This problem is called overfitting. A desirable model (a highly predictive model) is one that is simple and reproduces the existing data. Regularization is used to construct such a model. Taking a linear model as an example, we add a second term on the right-hand side of the following equation,

$$L = \sum_{i=1}^N \left\{ y^{(i)} - f(\mathbf{x}^{(i)}) \right\}^2 + \lambda \sum_{j=1}^d |w_j|^p,$$

where λ is a hyperparameter. Hyperparameters are parameters that are predetermined before the model is trained. When $p = 2$, it is called a ridge, and a linear regression with $p = 1$ is called “Least Absolute Shrinkage and Selection Operator (LASSO)” regression. In LASSO, certain coefficients are forced to zero, effectively selecting a simpler model that does not include these coefficients.

Descriptor

The numerical representation of materials is not unique. Therefore, the design of descriptors adapted for predictions is a major challenge in materials informatics. A simple example of a descriptor is as follows. Consider a binary material AB composed of elements A and B . Using the properties of the element A , e.g., atomic number Z_A , ionic radius R_A , ionization energy I_A , and similar quantities of the element B , Z_B , R_B , I_B , the material AB can be represented as $(Z_A, R_A, I_A, Z_B, R_B, I_B)$. In general, a material descriptor has multiple components. Extracting the important descriptors from these is an important issue for understanding the controlling factors of material properties.

In materials simulation, the design of descriptors related to atomic structure is generally important. Conventionally, atomic structures are represented in crystalline or Cartesian coordinates. However, this is not suitable for machine learning with structural information as input. This is because the coordinates vector is variable with respect to symmetry operations. For example, the total energy for an atomic configuration should be invariant to rotational and translational operations. However, when coordinates vector is used as descriptors, symmetry operations change their values, i.e., they are considered different data and will give a different energy. Therefore, descriptors must be invariant to symmetry operations. Additionally, dimension of the descriptor increases monotonically as the number of particles increases. In general, the more input dimensions there are, the more difficult machine learning becomes.

Instead, there are two types of atomic structure descriptors: system-wide descriptors and local descriptors. System-wide descriptors are often used to compare the total energy of molecules or crystals. For example, the simplified molecular input line entry system (SMILES) allows molecular structures to be represented as string series (Weininger, 1988). Molecular graphs are graph representations of molecular bonding networks. Several molecular fingerprints have also been proposed that encode the presence or absence of substructures in a molecular system.

Local descriptors, on the other hand, are well suited for molecular dynamics calculations with machine learning. Symmetry functions are typical examples of local descriptors. Symmetry functions (Behler and Parrinello, 2007, and Behler, 2015) quantify the structural information around an individual atom in a way that is invariant to symmetry operations. For example, the symmetry function for distance is expressed by the following equation,

$$G_i = \sum_{j \neq i}^{all \ atoms} e^{-\eta(R_{ij}-R_s)^2} \cdot f_c(R_{ij}),$$

where R_{ij} is the distance between atoms i and j , η and R_s are hyperparameters, and $f_c(r)$ is the cutoff function. This equation approximately represents the number of atoms in a spherical shell of radius R_s . The symmetry function vector, which combines the chosen symmetry functions of several hyperparameters and the symmetry function with respect to angles, is the descriptor around that atom as input of machine-learning potentials.

Machine-learning potentials

A machine learning potential is a surrogate model of first-principles calculations that uses atomic structure as input and outputs energy and forces acting on atoms. First-principles calculations based on DFT simulate total energy of a material and the forces nonempirically. On the other hand, the computational cost is typically proportional to the cube of the number of atoms, making it unsuitable for large-scale and complex systems such as catalytic reactions on surfaces or amorphous materials. Material simulations using classical potentials based on physical models are computationally efficient, but it is difficult to treat complex materials system with high accuracy. The machine learning potential is a solution that takes advantage of both benefits (Fig. 5).

There are various machine-learning models used to design the potentials. A typical example is the neural network potential, originally published in Behler and Parrinello (2007), which introduces a structural descriptor called symmetry functions as input and an architecture of neural network segmented by individual atoms. The symmetry functions are a descriptor that represents the local structure around atoms, which is invariant to the physically required translational and rotational symmetry. The symmetry functions are an important factor for the general-purpose neural network potentials. The error function for optimizing the model can be made more accurate by including force and virial coefficients as well as energy differences. ANI-1 potential proposed in Smith et al. (2017) targeting organic molecules also employs Behler-Parrinello type neural networks. Gaussian Approximation potential (Bartók et al., 2010) and moment tensor potential (Shapeev, 2016) are based on different regression approach. From an information-science perspective, MEGNet (Chen et al., 2019), M3GNet (Chen and Ong, 2022), and Pre-ferred Potential (Takamoto et al., 2022) based on graph neural networks have also been developed.

Fig. 5 Concept of the machine learning potentials.

Bayesian optimization

Bayesian optimization (BO), also called Kriging or black box optimization, have been originally used to predict a best place where mineral resources would be found. Indeed, it is impossible to survey all land for mineral resources. Then, a strategy is required from the limited data to predict the best place where to survey next. BO is one of the techniques. Several applications have been reported in the field of materials science. For example, Fukazawa et al. studied the problem of finding superior compositions in terms of magnetization, Curie temperature, and formation energy for disordered phases of rare earth transition metal compounds (Fukazawa et al., 2019). The results showed that using Bayesian optimization, the probability of finding a composition that exhibits the top 10 properties out of 3630 compositions within 50 times is more than 95%, which is much more efficient than the random sampling case (12.9%).

Researchers often search for the best experimental conditions by grid search, which is time-consuming and requires a great deal of experience. Especially, novice researchers with new equipment have no choice but to spend a great deal to find the best conditions. Therefore, BO has attracted hot attention as a technique to overcome this problem. The essence of BO is to estimate the optimal next choice from the obtained data. It is not suitable for case with the low data accumulation cost, but it is powerful in cases where it is difficult to collect exhaustive data within a limited time and financial cost, such as in material search and process optimization for synthesis.

BO can be understood in terms of two important processes. One is “prediction from existing data” and the other is “evaluation of candidates based on the prediction results” (Fig. 6). The former is based on a nonparametric method commonly referred to as Gaussian process regression. Unlike the kernel regression, Gaussian process regression (GPR) is formulated based on probability theory, so it can simultaneously evaluate the ambiguity of the prediction or credibility. For the evaluation of candidates based on the prediction results, we use an “acquisition function” to evaluate the quality of candidates based on predictions and their ambiguity and suggests candidates for the next observation point. In the following subsections, GPR and acquisition functions are introduced in detail.

Gaussian process regression

Gaussian process regression (GPR) is a non-parametric regression technique based on probability theory. GPR uses a high-dimensional Gaussian distribution as the generator of the regression curve. For example, suppose that an N-dimensional vector is sampled from an N-dimensional Gaussian distribution. This vector can be regarded as a 1-dimensional point series. By controlling the correlation between the points, this 1D point series can be made to form a smooth curve. The function controlling the correlation between the points is called the kernel function.

In Gaussian process regression, the regression model is created using the conditional probabilities under observed data points. When a curve randomly generated from a high-dimensional Gaussian distribution is restricted under the constraint that passes through the observed points, the mean curve is the regression model, and the variance of the conditional random curve is defined as the interval of the credibility. Regression curve $E(x)$ and credibility interval $V(x)$ is expressed as follows:

$$E(x) = \mathbf{k}^T (\mathbf{K} + \sigma^2 \mathbf{I}_n)^{-1} \mathbf{Y},$$

$$V(x) = k(x, x) - \mathbf{k}^T (\mathbf{K} + \sigma^2 \mathbf{I}_n)^{-1} \mathbf{k},$$

where σ is an estimated error of the regression model, $\mathbf{I}_n$ is a n -dimensional identity matrix and $\mathbf{Y}$ is the vector of the obtained objective data, respectively. The vector $\mathbf{k}$ and matrix $\mathbf{K}$ are corresponding to the kernel function $k(x, y)$, and their elements are expressed by the following equations,

Fig. 6 Bayesian optimization determines the next search point by considering not only the mean value but also the probability distribution. The values of x , y respectively stand for a descriptor and a target variable.

$$k_i = k(x_i, x), K_{ij} = k(x_i, x_j).$$

Acquisition functions

The acquisition function is an index for determining the next observation point. The Expected Improvement (EI) is a typical example of the acquisition function, which is the expectation value of improvement for target function y such as electronic conductivity. EI is given by following formula:

$$EI(x) = \int_{-\infty}^{y_{\min}} dy (y_{\min} - y) N[E(x), V(x)],$$

where $y_{\min}$ is the minimum target value that have been already obtained, and N is normal distribution.

Another typical acquisition function is Lower confidence bound (LCB), which evaluates the next candidates taking the balance between exploration and exploitation into consideration. The basic strategy of the acquisition function for this minimization is to evaluate the point with the lowest expected value $E(x)$ of the objective function in terms of exploitation. In addition to this, from the perspective of exploration, the point where the prediction is ambiguous, i.e., the point where the credit interval (standard deviation) is large, is also considered. The acquisition of LCB is expressed as follows:

$$LCB(x) = E(x) - \beta \sqrt{V(x)},$$

where β is the hyperparameter balancing the exploration and exploitation. In general, GP-UCB is often used where the parameters are automatically tuned.

Conclusion

Materials informatics has developed rapidly over the past decade. In the early days, the data handled by materials informatics were mainly computational data, but nowadays, data obtained by various experimental means are also treated. In general, the data available for materials development is limited, and the development of data creation techniques such as automated calculations and the introduction of robots is expected. In addition, the development of effective machine learning methods for small data and the utilization of materials expertise are also important issues.

Abstract

We present the basics of classical statistical mechanics, starting from the time averages of the macroscopic variables. We then move on to the Gibbs approach based on the phase space averages and introduce the microcanonical, canonical and grand canonical ensembles, applying the corresponding distributions to the ideal gas case. Finally, we briefly discuss the most modern developments in classical statistical mechanics, which have led to the study of statistical models for phase transitions.

Introduction

Statistical mechanics was created in the second half of nineteenth century as a branch of theoretical physics with the purpose of deriving the laws of thermodynamic systems from the equations of motion of their elementary constituents, i.e. atoms and molecules.

Its commonly recognized fathers were Rudolf Clausius (1822–1888), who first interpreted the heat as kinetic energy of molecules, James Clerk Maxwell (1831–1879), who derived the velocity distribution of the molecules in an ideal gas and, most important, Ludwig Boltzmann (1844–1906), who gave the entropy the statistical meaning.

Statistical mechanics was also the field where quantum physics first revealed itself: indeed, in 1900, Max Planck proposed the quantization hypothesis to give a statistical interpretation of the black body radiation.

Only 2 years later, Josiah Willard Gibbs (1839–1903) introduced the statistical-ensembles approach we commonly use today, allowing to extend statistical methods to a great variety of physical systems (Gibbs, 1902).

In the '20 of the twentieth century, the application of statistical methods to quantum mechanical systems gave rise to a substantially new discipline which was called *quantum statistical mechanics*; the theory elaborated up to that time and all its further developments not involving quantum mechanics (e.g. the study of statistical models and the theory of phase transitions and critical phenomena) were accordingly called *classical statistical mechanics*.

Usually, statistical mechanics deals with equilibrium phenomena and it should be called, more precisely, *equilibrium statistical mechanics*. Non-equilibrium phenomena are typically more difficult to study, but several important statistical treatments of them exist, starting with the famous and seminal Boltzmann-equation. These topics of *non-equilibrium statistical mechanics* are generally discussed as specific subjects directly related to their applications (e.g. transport phenomena, relaxation phenomena). Here we follow this habit. In the next sections we introduce the basics of *classical equilibrium statistical mechanics* in a concise but complete way. For further information, the reader can consult many excellent textbooks (Gallavotti, 1999; Khinchin, 1960; Ma, 1985; Reichl, 1998; Ruelle, 1999; Thompson, 1988; Toda et al., 1983).

Overview

Macroscopic and microscopic variables

The physical systems studied by statistical mechanics are composed of a very large (typically 10^{23}) number N of particles or degrees of freedom. In classical mechanics, the (microscopic) state of a system is univocally identified by giving the generalized positions q and momenta p of all the constituents.

For clarity sake, in the following we shall focus on a systems composed of N pointlike particles. We denote the $6N$ -tuple of all momenta and positions by (p, q) (or, when it is convenient to explicitly specify the number of particles, by $(p^{(N)}, q^{(N)})$), defining

$$(p, q) = (p^{(N)}, q^{(N)}) = (p_{1x}, p_{1y}, p_{1z}, \dots, p_{Nx}, p_{Ny}, p_{Nz}, q_{1x}, q_{1y}, q_{1z}, \dots, q_{Nx}, q_{Ny}, q_{Nz}).$$

The *microstate* (p, q) is therefore a point in the $6N$ dimensional *phase space* Ξ_N , which is the set of all possible physical states of the system.

According to classical dynamics, the time evolution of a system is determined by its Hamiltonian $H(p, q)$, and its coordinates $(p(t), q(t))$ satisfy the Hamilton equations

$$\frac{dp_i}{dt} = -\frac{\partial H}{\partial q_i} \quad \frac{dq_i}{dt} = \frac{\partial H}{\partial p_i}.$$

On the other hand, the macroscopic state (*macrostate*) of a system, which is the object of thermodynamics, is described by a very small number of macroscopic variables (e.g. volume, pressure, temperature); therefore it corresponds to many different microscopic states.

The macroscopic variables appearing in thermodynamic laws can be divided into two different categories: the mechanical (or, in more general systems, the magnetic, the electric etc.) and the statistical (or thermal) ones. The former can be calculated even for a single microstate from its (p, q) coordinates, i.e. they are functions $f(p, q)$ of the points of the phase space (for example, the internal energy). The latter cannot be determined for a single microstate, but we need all the microstates belonging to a given macrostate in order to calculate them, i.e. they are functions of subsets of the phase space (for example, the entropy).

Time averages

A fundamental assumption of classical statistical mechanics concerns the characteristic times of microscopic vs. macroscopic dynamics. It is assumed that the microscopic dynamics is much faster than the macroscopic one, so that during a macroscopic measurement (the measurement of a macroscopic variable) the systems assumes many different microstates (indeed, for continuous coordinates, infinite microstates). Therefore, the measured value of a mechanical macroscopic variable M is to be considered the *time average* $\bar{m}_t$ of the corresponding microscopic one m :

$$\bar{m}_t = \frac{1}{t} \int_0^t m(\tau) d\tau \quad (1)$$

t being the measurement duration. Considering that t is typically very large with respect to all characteristic times involved in microscopic dynamics, one takes the $t \rightarrow \infty$ limit, defining the macroscopic variable M as

$$M = \lim_{t \rightarrow \infty} \bar{m}_t \quad (2)$$

Even with this simplifying assumption, the problem of determining M would require the solution of the equations of motion for the system, unless we introduce some further hypotheses. These are connected with the *statistical equilibrium* condition, i.e. to the experimentally observed time-independence of macroscopic variables: first, we must suppose the limit in (2) exist; then, we have to require the independence of M from the specific microstate (belonging to the given macrostate) assumed by the system at the instant $t = 0$, formally chosen as the beginning of the measurement.

Phase space averages

A crucial technical step in the development of classical statistical mechanics is the passage from time averages to phase-space averages. To introduce it, we consider that in classical mechanics every mechanical variable m is a function $m(p, q)$ of the phase space coordinates p and q . Therefore, to calculate time averages we could simply ask how many times the system has visited each point in phase space (or, more precisely, an infinitesimal volume $dpdq$ around that point); associating to every point (p, q) a weight $\rho(p, q)$ proportional to the number of visits, we can then obtain the time average of any variable m by computing its weighted average on the phase space points. These heuristic considerations can be mathematically formalized as follows (assuming all the conditions for the interchange of the integrals and the limit hold)

$$\begin{aligned} M &= \lim_{t \rightarrow \infty} \frac{1}{t} \int_0^t m(p(\tau), q(\tau)) d\tau = \lim_{t \rightarrow \infty} \frac{1}{t} \int_0^t \left[\int m(p, q) \delta(p - p(\tau)) \delta(q - q(\tau)) dp dq \right] d\tau = \\ &= \int m(p, q) \left[\lim_{t \rightarrow \infty} \frac{1}{t} \int_0^t \delta(p - p(\tau)) \delta(q - q(\tau)) d\tau \right] dp dq \equiv \\ &\equiv \int m(p, q) \rho(p, q) dp dq \end{aligned} \quad (3)$$

where

$$\rho(p, q) \equiv \lim_{t \rightarrow \infty} \frac{1}{t} \int_0^t \delta(p - p(\tau)) \delta(q - q(\tau)) d\tau \quad (4)$$

with $dp \equiv dp_{1x} \cdots dp_{Nz}$ and $dq \equiv dq_{1x} \cdots dq_{Nz}$.

Notice that the introduction of $\rho(p, q)$ allows us to calculate the average values of any mechanical variable without knowing its dynamics: in other words, once $\rho(p, q)$ is known, we can completely neglect the time in all further calculations.

From the requirements introduced at the end of the last section, and from the generality of M , it follows that the function $\rho(p, q)$ only depends on and completely determines the macrostate it corresponds to. Therefore it must parametrically depend only on the restricted number of macroscopic variables defining that macrostate. The same requirements would imply that, for any starting point (p, q) belonging to the macrostate, the system visits all the microstates belonging to it and that the frequency of visits is $\rho(p, q)$. This property cannot be proven for a generic dynamical system, and it has to be considered as one of the fundamental assumptions of classical statistical mechanics.

The statistical ensembles

The calculation of $\rho(p, q)$ from its definition would imply the complete solution of the equations of motion with any initial condition. This is in practice impossible even for simple systems, due to the large number of degrees of freedom. In fact, $\rho(p, q)$ was determined in a general form once and for all by Gibbs for the most significant cases, on the basis of physical considerations and assumptions.

Gibbs followed an alternative approach. Instead of just one system, he considered a large set of physically identical systems at once, all having the same Hamiltonian but being in different microstates at a given time t , and he assumed they representative points (p, q) in phase space were distributed with a density $\rho(p, q)$. He called such a set a *statistical ensemble* and $\rho(p, q)$ its *distribution*. In other word, each system in the ensemble is, at time t , in a microscopic state (p, q) corresponding to the macroscopic state described by $\rho(p, q)$, with a probability given by $\rho(p, q)$ itself. Then he imposed the *statistical equilibrium condition* by requiring that the density of the points representing the systems in the phase space was left invariant during their time evolution. Finally, he proved that this condition is fulfilled if and only if

$$\rho(p, q) = f(H(p, q)) \quad (5)$$

i.e. if and only if $\rho(p, q)$ depends on the phase space coordinates p and q only through the Hamiltonian of the system.

Now, considering the typical macroscopic constraints characterizing a thermodynamic system, he identified three main general kinds of ensembles and, using (5) and some specific hypotheses, he calculated their distributions. Gibbs called these ensembles *microcanonical*, *canonical* and *grand canonical* and these names have been used ever since.

The microcanonical ensemble

Even if Gibbs first considered the canonical ensemble and then he derived the microcanonical one from it, the following formal development of statistical mechanics suggested inverting the order, to have a stronger connection with the microscopic dynamical equations.

The microcanonical ensemble describes a closed isolated system, i.e. a system which cannot exchange particles and energy with the external world, confined in a fixed volume. Therefore, the macroscopic variables characterizing it are the number of particles N , the volume V and the total energy E . Notice that all of them are mechanical variables: indeed, the microcanonical ensemble is the statistical ensemble which is most directly connected with a classical dynamical system. The variables N , V and E are also all extensive, i.e. they are asymptotically proportional to the number of degrees of freedom (usually $3N$) for large N . Many physical properties of thermodynamic systems turn out to be simpler by taking the *thermodynamic limit* $N \rightarrow \infty$; in that case we shall require that the ratios of V and E to N (called the *specific volume* and the *specific energy* respectively) are constant in this limit:

$$\lim_{N \rightarrow \infty} \frac{V}{N} = v; \quad \lim_{N \rightarrow \infty} \frac{E}{N} = \varepsilon \quad (6)$$

Due to its defining conditions, the energy of each system belonging to the microcanonical ensemble is constant during time evolution; in other words, its trajectory in phase space entirely lies on the hypersurface $H(p, q) = E$. The microcanonical distribution is obtained assuming $\rho(p, q)$ is constant on this hypersurface and zero elsewhere:

$$\rho_{N,V,E}^{\mu C}(p, q) = \frac{\varepsilon_0 \delta(E - H(p, q))}{\Gamma(N, V, E)} \quad (7)$$

where

$$\Gamma(N, V, E) = \varepsilon_0 \int \delta(E - H(p, q)) dp dq \quad (8)$$

is the measure of the region of the phase space accessible to the system, i.e. it measures how large is the set of microstates corresponding to the given macrostate identified by N, V and E , and ε_0 is an arbitrary but fixed constant with the dimension of an energy, which is convenient to introduce to give Γ the dimension of a volume in phase space (without loss of generality, we can set it equal to 1).

The assumption leading to (7) means that the system, in its motion, explores “in a uniform way” the whole constant-energy hypersurface. Many attempts have been made during the last century to mathematically prove this hypothesis to be a consequence of general properties of Hamiltonian dynamical systems. However this problem, known as the *ergodic problem*, has not been solved but for a very restricted class of systems (typically hard-spheres gases), and we will consider the *ergodic hypothesis* a reasonable assumption leading to experimentally verifiable results.

Knowing the microcanonical distribution $\rho_{N,V,E}^{\mu C}(p, q)$, it is possible to calculate the average of any mechanical variable according to (3). However, we have no rule to calculate the fundamental thermal variables, such as the entropy S and the temperature T . In order to connect the microcanonical distribution with the thermodynamics, we have to introduce the most important postulate of all statistical mechanics, namely the Boltzmann relation, which derives the entropy from Γ :

$$S(N, V, E) = k_B \ln \frac{\Gamma(N, V, E)}{\Gamma_0} \quad (9)$$

where $k_B = 1.3807 \cdot 10^{-23} \text{ JK}^{-1}$ is the Boltzmann constant and Γ_0 is a fixed but arbitrary number with the same dimensions as Γ . It represents a unit of measure for volumes in phase space and it is necessary to make the argument of the logarithm adimensional. Notice that it does not make the definition (9) ambiguous, since the entropy, like every thermodynamic potential, is always defined up to an arbitrary additive constant. As it is well known, this arbitrariness can be eliminated by introducing the so called *third principle of thermodynamics*, or *Nernst postulate*, according to which the entropy must vanish for $T \rightarrow 0$: this requirement univocally fix the value of Γ_0 . Moreover, in order to have a coherent definition of Γ_0 for different values of N when taking the thermodynamic limit, it is customary to choose once for all the unit of measure γ for the smallest phase space, corresponding to only one particle in one dimension, and then define $\Gamma_0(N)$ for a system of N particles (in three dimensions) as

$$\Gamma_0(N) = \gamma^{3N} \quad (10)$$

Considerations based on the semiclassical limit of quantum mechanics suggest then to chose $\gamma = h$, where h is the Plank constant, but this is outside the proper domain of classical statistical mechanics.

The Boltzmann relation cannot be mathematically proven and we have to consider it a postulate.

All that we can do is proving that, under some restrictive hypotheses, the *statistical entropy* defined by (9) has the same mathematical properties of the *thermodynamic entropy* defined by the differential relation $dS = dQ/T$. The fundamental of these hypotheses concerns the interactions between the particles in the system: they must decay rather fast with increasing distance. More precisely, supposing the interactions isotropic for simplicity sake, the interaction potentials $V(r)$ must decay faster than r^{-2} as $r \rightarrow \infty$. This means that we cannot apply equilibrium statistical mechanics to systems with (non negligible) gravitational interactions as well as to systems containing electrically charged particles and having non-zero total charge.

An important modification to (9) has to be introduced if the particles of the system are indistinguishable. Indeed, many years before the quantum concept of identical particles was introduced, Gibbs proved that Γ needs to be divided by $N!$ in order to preserve the asymptotic additivity of the entropy (his argument is commonly know as the *Gibbs paradox*):

$$S(N, V, E) = k_B \ln \frac{\Gamma(N, V, E)}{\Gamma_0 N!} \quad (11)$$

In the most general case, not all the particles are indistinguishable, but we can have N_1 indistinguishable particles of one kind, N_2 of a different kind and so on. If the system is composed of m different kinds of indistinguishable particles, with $\sum_{i=1}^m N_i = N$, (allowing even $N_i = 1$ for generality sake), the most general expression of the entropy is given by

$$S(N_1, \dots, N_m, V, E) = k_B \ln \frac{\Gamma(N_1, \dots, N_m, V, E)}{\Gamma_0 N_1! \dots N_m!} \quad (12)$$

A slightly different definition of the microcanonical ensemble can be found in literature, according to which the systems belonging to the ensemble have energy between E and $E + \Delta E$ instead of exactly E . Assuming a constant distribution in the entire phase space region satisfying that constraint, and defining Γ to be the volume of this region, one can again define S using (12). It can be shown that in the thermodynamic limit the two definitions of the entropy are asymptotically equivalent and the corresponding distributions give the same thermodynamic behavior.

Eq. (12) is the starting point for deriving all the thermodynamics of the microcanonical ensemble. Applying basic thermodynamic relations we obtain

$$\frac{1}{T} = \left. \frac{\partial S}{\partial E} \right|_{V, N_1, \dots, N_m} \quad (13)$$

$$\frac{P}{T} = \left. \frac{\partial S}{\partial V} \right|_{E, N_1, \dots, N_m} \quad (14)$$

$$\frac{\mu_i}{T} = - \left. \frac{\partial S}{\partial N_i} \right|_{V, E} \quad (15)$$

giving the *temperature*, the *pressure* and the *chemical potentials* respectively.

The canonical ensemble

The most typical system studied in statistical mechanics is confined in a fixed volume and is closed, but it is not isolated and it can exchange energy with a thermal bath (or a *reservoir*) at a fixed temperature. It is described by the canonical ensemble and the macroscopic variables characterizing it are the number of particles N , the volume V and the temperature T .

We can consider it as a small but macroscopic subsystem of a closed isolated system, the remaining part of which acts as reservoir. Therefore, we can obtain the *canonical distribution* from the microcanonical one, calculating the distribution of a closed subsystem whose volume and number of particles in the thermodynamic limit satisfy

$$\lim_{N \rightarrow \infty} \frac{V}{N} = v; \quad \lim_{N \rightarrow \infty} \frac{N}{N_{TOT}} = \lim_{N \rightarrow \infty} \frac{V}{V_{TOT}} = 0 \quad (16)$$

N_{TOT} and V_{TOT} being the number of particles and the volume of the whole closed isolated system.

Introducing, as usual, some suitable hypotheses (e.g. the ratio between the external surface of the subsystem and its volume must vanish in the thermodynamic limit) after some calculations we get

$$\rho_{N,V,T}^C(p, q) = \frac{e^{-\frac{H(p,q)}{k_B T}}}{Z(N, V, T)} \quad (17)$$

where

$$Z(N, V, T) = \int e^{-\frac{H(p,q)}{k_B T}} dp dq \quad (18)$$

is called the *canonical partition function*.

For the canonical ensemble, Z plays a role analogous to Γ for the microcanonical one: it is a sort of normalization factor which is not directly measurable but it is the starting point for deriving all the thermodynamic quantities. The basic relation connecting it to a thermodynamic potential is

$$F(N, V, T) = -k_B T \ln \frac{Z(N, V, T)}{Z_0} \quad (19)$$

F being the *Helmholtz free energy* and Z_0 an arbitrary constant with the same dimensions as Z , playing the same role of Γ_0 in (9); indeed, F too is defined up to an additive constant like S and the arbitrariness can be eliminated in the same way assuming the third principle of thermodynamics to hold. Moreover, the same considerations introduced for Γ_0 , concerning the normalization in the thermodynamic limit and the presence of indistinguishable particles, apply. Accordingly, the general form of (19) becomes

$$F(N_1, \dots, N_m, V, T) = -k_B T \ln \frac{Z(N_1, \dots, N_m, V, T)}{Z_0(N) N_1! \dots N_m!} \quad (20)$$

with

$$Z_0(N) = \gamma^{3N} \quad (21)$$

After determining F by (20), all the thermodynamics of the canonical ensemble can be easily deduced. The main thermodynamic equations we need are

$$S = -\left. \frac{\partial F}{\partial T} \right|_{V, N_1, \dots, N_m} \quad (22)$$

$$P = -\left. \frac{\partial F}{\partial V} \right|_{T, N_1, \dots, N_m} \quad (23)$$

$$\mu_i = \left. \frac{\partial F}{\partial N_i} \right|_{V, T} \quad (24)$$

$$E = F + TS \quad (25)$$

where E denotes the *internal energy* and coincides with the average value of the Hamiltonian.

The grand canonical ensemble

The case of a system occupying a fixed volume but exchanging particles and energy with the external world, at fixed temperature and chemical potentials, is described by the *grand canonical ensemble*. In the simplest situation, all the particles are of the same kind and a macrostate is as usual defined by three macroscopic variables, the volume V , the temperature T and the chemical potential μ (representing the energy increment due to the addition of a particle). However, a microstate is no longer represented by a point in a usual phase space. Indeed, the dimension of the phase space depends on the number of particles N , and here N is variable.

To face this problem, we have to introduce an extended space Ξ given by the union of the phase spaces Ξ_N corresponding to all possible N

$$\Xi = \bigcup_{N=0}^{\infty} \Xi_N \quad (26)$$

A point in this space is given by the $6N + 1$ -tuple $(N, p^{(N)}, q^{(N)})$, i.e. by the number of particles N and a point in the corresponding phase space Ξ_N (notice that we have to include the case $N = 0$, corresponding to an empty system). For any N we have also to consider a specific Hamiltonian $H_N(p^{(N)}, q^{(N)})$ and, to have a coherent definition of volumes in phase spaces of different dimensions, we chose the volume unit $Z_0(N) = \gamma^{3N}$ according to (21).

To obtain the *grand canonical distribution*, we can follow a procedure similar to that we have used to derive the canonical distribution from the microcanonical one.

We consider a small but macroscopic subsystem of a closed isolated system, the remaining part of which acts as reservoir of energy and particles. The subsystem is open (it can exchange particles and energy with the external world), but it occupies a fixed volume V in space. We assume that, taking the thermodynamic limit,

$$\lim_{V \rightarrow \infty} \frac{V}{V_{TOT}} = 0 \quad (27)$$

where V_{TOT} is the volume of the whole closed isolated system, and that the ratio between the external surface of the subsystem and its volume also vanish in the thermodynamic limit.

After some algebra we obtain

$$\rho_{\mu, V, T}^{GC}(N, p^{(N)}, q^{(N)}) = \frac{e^{\frac{\mu N - H_N(p^{(N)}, q^{(N)})}{k_B T}}}{\gamma^{3N} N! Z^{GC}(\mu, V, T)} \quad (28)$$

where

$$Z^{GC}(\mu, V, T) = \sum_{N=0}^{\infty} \frac{e^{\frac{\mu N}{k_B T}}}{\gamma^{3N} N!} \int e^{-\frac{H_N(p^{(N)}, q^{(N)})}{k_B T}} dp^{(N)} dq^{(N)} \quad (29)$$

is the *grand canonical partition function* or *grand partition function*. The last expression can also be written as

$$Z^{GC}(\mu, V, T) = \sum_{N=0}^{\infty} \frac{z^N Z(N, V, T)}{\gamma^{3N} N!} \quad (30)$$

in terms of the canonical partition functions $Z(N, V, T)$ and of the *activity* z , defined by

$$z = e^{\frac{\mu}{k_B T}} \quad (31)$$

In the most general case of a system composed of m different kinds of indistinguishable particles, we have to introduce a different chemical potential for each kind of particle, therefore the macroscopic variables characterizing a macrostate are T, V , and the m chemical potentials $\mu_1, \dots, \mu_m$.

As for the microstates, we have to specify the number N_i of particles of each kind $i = 1, \dots, m$, and introduce the corresponding phase space $\Xi_{N_1, \dots, N_m}$ with coordinates $(p^{(N_1, \dots, N_m)}, q^{(N_1, \dots, N_m)})$. Accordingly, the extended space Ξ of (26) becomes

$$\Xi = \bigcup_{N_1=0}^{\infty} \dots \bigcup_{N_m=0}^{\infty} \Xi_{N_1, \dots, N_m} \quad (32)$$

and a point of Ξ is specified by the coordinates $(N_1, \dots, N_m, p^{(N_1, \dots, N_m)}, q^{(N_1, \dots, N_m)})$ while the Hamiltonian acting on it is $H_{N_1, \dots, N_m}(p^{(N_1, \dots, N_m)}, q^{(N_1, \dots, N_m)})$.

Using this notation, the grand canonical partition function is given by

$$\begin{aligned} \rho_{\mu_1, \dots, \mu_m, V, T}^{GC}(N_1, \dots, N_m, p^{(N_1, \dots, N_m)}, q^{(N_1, \dots, N_m)}) &= \\ &= \frac{\sum_{i=1}^m \mu_i N_i - H_{N_1, \dots, N_m}(p^{(N_1, \dots, N_m)}, q^{(N_1, \dots, N_m)})}{e^{k_B T}} \\ &= \frac{\sum_{i=1}^m N_i}{\gamma} \frac{1}{N_1! \dots N_m!} Z^{GC}(\mu_1, \dots, \mu_m, V, T) \end{aligned} \quad (33)$$

with

$$\begin{aligned} Z^{GC}(\mu_1, \dots, \mu_m, V, T) &= \\ &= \sum_{N_1=0}^{\infty} \dots \sum_{N_m=0}^{\infty} \prod_{i=1}^m \frac{z_i^{N_i}}{\gamma^{3N_i} N_i!} \int e^{-\frac{H_{N_1, \dots, N_m}(p^{(N_1, \dots, N_m)}, q^{(N_1, \dots, N_m)})}{k_B T}} dp^{(N_1, \dots, N_m)} dq^{(N_1, \dots, N_m)} \end{aligned} \quad (34)$$

and

$$z_i = e^{\frac{\mu_i}{k_B T}} \quad (35)$$

The thermodynamics of the grand canonical ensemble can be derived from the basic equation

$$\Omega(\mu_1, \dots, \mu_m, V, T) = -k_B T \ln Z^{GC}(\mu_1, \dots, \mu_m, V, T) \quad (36)$$

where the thermodynamic potential Ω is defined by

$$\Omega = -PV \quad (37)$$

The other thermodynamic quantities are obtained from Ω applying the relations

$$S = -\frac{\partial \Omega}{\partial T} \bigg|_{V, \mu_1, \dots, \mu_m} \quad (38)$$

$$N_i = -\frac{\partial \Omega}{\partial \mu_i} \bigg|_{V, T} \quad (39)$$

$$E = \Omega + TS + \sum_{i=1}^m \mu_i N_i \quad (40)$$

where N_i denotes the average number of particles of kind i .

The perfect gas

The simplest and best known application of classical statistical mechanics concerns the so called perfect gas, i.e. a system of non-interacting particles. This is obviously an ideal case, since a complete absence of interaction would prevent a system from reaching the equilibrium, but we can consider it a good approximation for rarefied real gases, where the potential energy is negligible with respect to the kinetic energy. It also represents the natural starting point for the study of more complicated systems by perturbative techniques.

Choosing, for simplicity sake, a monatomic gas composed of indistinguishable pointlike particles of only one kind, the perfect gas Hamiltonian is

$$H_N(p^{(N)}, q^{(N)}) = \sum_{i=1}^N \frac{\mathbf{p}_i^2}{2m} \quad (41)$$

with $\mathbf{p}_i = (p_{ix}, p_{iy}, p_{iz})$ and m being the mass of each particle.

Microcanonical ensemble

Let us study first the case of a closed isolated system, described therefore by the microcanonical ensemble. We suppose the gas confined in a fixed space volume V and with a fixed energy E and number of particles N .

To calculate the thermodynamic properties of such a system we have first to determine its entropy according to (11) and to do that we need the measure $\Gamma(N, V, E)$ of the region of the phase space accessible to the system:

$$\Gamma(N, V, E) = \varepsilon_0 \int \delta(E - H(p, q)) dp dq = \varepsilon_0 V^N \int \delta\left(E - \sum_{i=1}^N \frac{\mathbf{p}_i^2}{2m}\right) d\mathbf{p}_1 \cdots d\mathbf{p}_N \quad (42)$$

After some straightforward steps we obtain

$$\Gamma(N, V, E) = \frac{\varepsilon_0 V^N (E)^{3N/2-1} (2m\pi)^{3N/2}}{\Gamma_{Eul}(3N/2)} \quad (43)$$

and, substituting in (11) and using (10),

$$S(N, V, E) = k_B \ln \frac{\varepsilon_0 V^N (E)^{3N/2-1} (2m\pi)^{3N/2}}{\Gamma_{Eul}(3N/2) \gamma^{3N} N!} \quad (44)$$

which, for $N \rightarrow \infty$ and using the definitions (6), gives the asymptotic expression

$$S(N, V, E) \approx k_B N \left(5/2 + \ln \frac{(4m\pi/3)^{3/2} v}{\gamma^3} \right) \quad (45)$$

Notice that the entropy (45) is extensive as expected, due to the Gibbs factor $N!$ introduced in (11).

Finally, applying (13), (14) and (15), we obtain the usual thermodynamic equations for the perfect monatomic gas

$$\frac{1}{T} = \frac{3}{2} \frac{k_B}{\varepsilon} \quad (46)$$

$$\frac{P}{T} = \frac{k_B}{v} \quad (47)$$

$$\frac{\mu}{T} = -k_B \ln \frac{(4m\pi/3)^{3/2} v}{\gamma^3} \quad (48)$$

Notice that, due to the presence of the arbitrary normalization constant γ , the chemical potential is not univocally defined unless one introduces the third principle of thermodynamics or quantum mechanical arguments (see the comments to Eqs. (9), (10)).

Canonical ensemble

Let us now consider the perfect monatomic gas composed of N particles in a fixed volume V , in thermal equilibrium with a reservoir at temperature T . This system is described by the canonical ensemble and to calculate its thermodynamics we need the partition function Z defined in (18).

Calculating Z for the Hamiltonian (41) we obtain

$$\begin{aligned} Z(N, V, T) &= \int e^{-\frac{H(p,q)}{k_B T}} dp dq = V^N \int e^{-\sum_{i=1}^N \frac{\mathbf{p}_i^2}{2mk_B T}} d\mathbf{p}_1 \cdots d\mathbf{p}_N = \\ &= V^N (2\pi mk_B T)^{\frac{3N}{2}} \end{aligned} \quad (49)$$

and, applying (20) for $m = 1$ and $N \rightarrow \infty$,

$$F(N, V, T) = -k_B T \ln \frac{Z(N, V, T)}{N! \gamma^{3N}} \approx -k_B T N \ln \left(e v (2\pi mk_B T \gamma^{-2})^{\frac{3}{2}} \right) \quad (50)$$

Again, the Helmholtz free energy is extensive due to the Gibbs factor $N!$

The main thermodynamic equations are then given by Eq. (22)–(25):

$$S = N k_B \ln \left(e^{\frac{5}{2}} v (2\pi mk_B T \gamma^{-2})^{\frac{3}{2}} \right) \quad (51)$$

$$P = \frac{k_B T}{v} \quad (52)$$

$$\mu = -k_B T \ln \left(v (2\pi m k_B T \gamma^{-2})^{\frac{3}{2}} \right) \quad (53)$$

$$E = \frac{3}{2} N k_B T \quad (54)$$

Grand canonical ensemble

Finally, we study the case of a perfect monatomic gas in a fixed volume V , exchanging energy and particles with a reservoir at fixed T and μ . Using expression (30) for the grand canonical partition function, with $Z(N, V, T)$ given by (49), we obtain

$$\begin{aligned} Z^{\text{GC}}(\mu, V, T) &= \sum_{N=0}^{\infty} \frac{z^N Z(N, V, T)}{\gamma^{3N} N!} = \sum_{N=0}^{\infty} \frac{z^N V^N (2\pi m k_B T)^{\frac{3N}{2}}}{\gamma^{3N} N!} = \\ &= e^{zV(2\pi m k_B T \gamma^{-2})^{\frac{3}{2}}} \end{aligned} \quad (55)$$

and, from (36) and (37),

$$\Omega = -PV = -k_B z V T^{\frac{5}{2}} (2\pi m k_B \gamma^{-2})^{\frac{3}{2}} \quad (56)$$

while the thermodynamic relations given by Eq. (38)–(40) are

$$S = \left(\frac{5}{2} - \frac{\mu}{k_B T} \right) k_B z V (2\pi m k_B T \gamma^{-2})^{\frac{3}{2}} \quad (57)$$

$$N = z V (2\pi m k_B T \gamma^{-2})^{\frac{3}{2}} \quad (58)$$

$$E = \frac{3}{2} k_B T z V (2\pi m k_B T \gamma^{-2})^{\frac{3}{2}} \quad (59)$$

The thermodynamic equations derived for the three ensembles have obviously different meanings, since they refer to different physical situations. Indeed, quantities which are fixed in one of the ensemble can be fluctuating in a different ensemble (e.g. E is fixed in the microcanonical and fluctuating in the other ensembles). However, if we consider the average values of the fluctuating quantities, all these equations becomes equivalent from a mathematical point of view, allowing a unified thermodynamic description. From a physical point of view this makes sense as far as the fluctuations around the average values are negligible with respect to the average values themselves or, in other words, as far as the *relative fluctuations* vanish.

This can be shown to happen usually in the thermodynamic limit, with the important exception of systems near critical point, where even the relative fluctuations typically diverge.

Key issues

Statistical models

Although classical statistical mechanics has as its starting point the time averages on the evolution of a system in phase space, Gibbs' innovative approach, over the course of the twentieth century, paved the way for applications that go beyond its initial scope.

The ensemble average, understood as the average over a set of microstates, each weighted with an appropriate probability, in fact, can be extended to very different systems than those initially described by Gibbs himself.

The key point is to replace the concept of microstate with that of configuration, where, by configuration, we mean the set of values assumed by the microscopic variables that describe the system.

An energy is associated with each configuration, through a function defined Hamiltonian, in analogy with the canonical case, even if, technically, it does not have the properties of the Hamilton function in classical mechanics. In particular, here the conjugate variables p and q do not exist in general, and it is not possible to derive the dynamics of the system from the Hamiltonian, as it happens instead in the canonical case. Indeed, in general these systems are studied without any reference to the dynamic properties, implying that the average on the configurations should be equivalent to the time average on a dynamics which is not explicitly defined. This implies, among other things, that the term corresponding to kinetic energy is normally missing in the Hamiltonian. This lack can also lead to surprising results compared to what is found in the canonical approach. Among these, one of the most interesting is the existence of systems with negative temperatures, which, among other things, have an experimental equivalent in population inversion systems, such as lasers (Ramsey, 1956). This phenomenon is found by applying microcanonical statistics to systems in which the number of configurations corresponding to a given energy decreases as the energy increases, an impossible situation in the presence of the kinetic term in the Hamiltonian. Since the temperature is given by the inverse of the derivative of entropy with respect to energy (13), it follows that this decrease, producing a negative derivative, gives rise to negative temperatures.

Statistical models, unlike classical statistical systems, are not born with the aim of calculating exactly the macroscopic physical quantities that characterize the system they describe. Their nature is approximate by definition: details are neglected, and we focus

only on the essential aspects. Their importance lies in the fact that they are able to give very general qualitative (and in some cases also quantitative) predictions on the behavior of the real systems they approximate. The most typical example of application concerns phase transitions, in particular magnetic ones. In this case, the predictive power of these models derives from the properties of universality, which were highlighted mainly in the second half of the twentieth century.

To discuss in more detail the function and properties of statistical models, we now focus on perhaps the most representative case, namely spin models.

Classical spin models

In a classical spin model, each site i of a lattice is associated with a variable σ_i which represents the value of the spin at that site. These models were originally introduced to describe the magnetic behavior of crystalline structures but have since been extended to more general systems. A system configuration, in this case, is represented by the set of values assumed by the variables σ_i in each site and is symbolically indicated with $\{\sigma_i\}$.

Historically, the first spin model to be introduced was the Ising model (Lenz, 1920), in which each variable σ_i can only assume the values $+1$ and -1 . Later, this approach was extended to more general models, in which the variables σ_i can assume a larger number of values or represent vector variables.

The typical Hamiltonian of a spin model can be written in the general form

$$H(\{\sigma_i\}) = -\sum_{i,j} J_{ij} \sigma_i \cdot \sigma_j - \sum_i h_i \cdot \sigma_i \quad (60)$$

where the variables σ_i can be scalars or vectors, h_i represents a local (magnetic) field of the same nature (scalar or vector) as the σ_i , and J_{ij} , called the coupling matrix, is a real symmetric matrix whose elements describe the interaction between the variables σ_i and σ_j .

Normally, the coupling matrix is determined by the geometry or topology of the structure on which the spin variables are located. On a lattice with first-neighbor interactions, for example, $J_{ij} \neq 0$ only if i and j are nearest neighbor sites. In the simplest cases, commonly studied, we assume to have the same coupling between each pair of nearest neighbors and the same local magnetic field in each site: $J_{ij} = J$ and $h_i = h$, with $J > 0$ if the model describes a ferromagnetic system and $J < 0$ in the antiferromagnetic case.

In general, statistical models, and spin models in particular, despite their simplified nature, are not exactly soluble with analytical tools (Baxter, 2008; Mussardo, 2020), with an important exception represented by the Ising model on a two-dimensional lattice (Onsager, 1944). To study them one can resort to further analytical approximations, or to numerical simulations, as happens more frequently since the computing power of computers reached levels that were unthinkable a few decades ago.

Nevertheless, as mentioned previously, a series of rigorous theorems allows us to obtain very valuable and useful information on the behavior of these models and the systems they describe.

Phase transitions and universality classes

The most important point concerns the universality property, according to which the behavior of the models as far as phase transitions are concerned, depends exclusively on the dimension of the lattice on which they are defined, and on the nature of the symmetry of the Hamiltonian (more precisely, on the transformations of the spin variables that leave the Hamiltonian invariant when $h = 0$). From a mathematical point of view, a ferromagnetic phase transition can only occur on infinite lattices and what we are going to say has to be understood as referring to this type of lattice. Discrete symmetry models (scalar spin variables), such as the Ising model, may exhibit ferromagnetic phase transitions, with non-zero spontaneous magnetization at zero magnetic field h , and at $T > 0$, if and only if the lattice dimension d is greater or equal to 2 (Peierls, 1936), while those with continuous symmetry can have ferromagnetic phase transitions at $T > 0$ if and only if the lattice dimension d is greater than or equal to 3 (Mermin and Wagner, 1966; Fröhlich et al., 1976). Furthermore, in the case of second order phase transitions and critical phenomena, also the critical exponents that describe the behavior of the system only depend on the lattice dimension and the symmetry of the Hamiltonian. The importance of these results, beyond their theoretical interest, also lies in their practical and applicative implications. In fact, if some relevant quantities do not depend on the details of the system, such as the exact value of the couplings or the presence of defects in a crystal lattice, but only on those extremely general characteristics which are the lattice size and the Hamiltonian symmetry, then it is possible to obtain those quantities by calculating them, analytically or numerically, for the simplest possible model that has the same characteristics.

All models exhibiting the same critical behavior form a universality class.

Using this terminology, we can say that the universality classes are only determined by the lattice dimension and the symmetry of the Hamiltonian and that, to know the critical exponents of a given model, it is sufficient to know those of any other model in the same universality class.

Statistical models on general networks

In more recent times, the study of statistical models has been extended from lattices to more complex structures represented by graphs or networks (Burioni et al., 2004). These models are useful for describing, for example, the behavior of non-crystalline

structures such as amorphous materials, polymer gels, fractals, or generic disordered structures. In these cases, the concept of lattice size is missing, or it can be misleading, lacking translational invariance, from which most of the properties of crystal lattices derive. However, through a series of analytical studies, it was possible to identify some universal parameters, linked to the geometry or large-scale topology of the structures, which allow to extend the classification into universality classes also to these systems.

The key point for solving these problems consists in noting that the coupling matrix J_{ij} is in fact an algebraic description of the topology of the structure and can be used to describe not only the interactions between spins in statistical models, but also different physical phenomena, such as diffusion, harmonic oscillations or the electrical properties of the structure. Without going into details, we limit ourselves to saying that it is possible to define a new topological parameter, called the spectral dimension, $\tilde{d}$, defined, referring to the density of acoustic vibrational modes of the structure $\rho(\omega)$ at low frequencies ω , by the relation (Alexander and Orbach, 1982)

$$\rho(\omega) \sim \omega^{\tilde{d}-1} \quad (61)$$

The spectral dimension $\tilde{d}$ coincides with the usual dimension d in the case of lattices, while, in the more general case of connected real structures, it can assume real values between 1 and 3. It can be calculated, numerically and in some cases analytically, in the case of graph models, while it can be experimentally measured in the case of real structures, using neutron scattering, low temperature calorimetry and other related techniques.

The spectral dimension plays a similar role to the dimension d of lattices in the case of continuous symmetry models. The latter present phase transitions at $T > 0$ if and only if $\tilde{d} > 2$ (Cassi, 1992; Burioni et al., 1999) and the corresponding universality classes are determined by $\tilde{d}$ and by the symmetry of the Hamiltonian.

The case of discrete symmetry models, on the other hand, has not yet been completely solved. It is known for certain that, for these models, the spectral dimension is not the relevant parameter for determining phase transitions. There are some rigorous theorems that link the presence or absence of phase transitions to other topological parameters (Campari and Cassi, 2010, 2011), but a necessary and sufficient condition, similar to that determined by the spectral dimension in the case of continuous symmetries, has not yet been found. The field of research in this sector is still very open.

Conclusion

In the previous sections we examined the foundations of classical statistical mechanics, established in the nineteenth century through the definition of time averages. We then showed how Gibbs' innovative approach, based on the averages on the sets, has allowed an extremely more efficient formal evolution, and we applied the Gibbs statistical sets to the case of the perfect gas. Subsequently, we dealt with the more modern evolution of classical statistics which led to the study of so-called statistical models, which are particularly useful in the study of phase transitions and critical phenomena, both on the lattice and on more complex and irregular structures.

In recent years, the application of statistical models and the methods used for their study has been extended to increasingly vast sectors, which go beyond physics itself, such as economics, ecology, sociology, and others (Park et al., 2012; Fort, 2020; Chakrabarti and Sen, 2014). The basic idea consists in describing all the possible states of a generic system through a set of variables, introducing a function similar to the Hamiltonian that determines the probability of each state. In this case, the initial meaning of the Gibbs distributions and their relationship with thermodynamics is obviously lost. Nonetheless, the parallel with the results obtained for true physical models is extremely useful for understanding the behavior of these non-physical systems.

The main problem of classical statistical mechanics and its extensions remains the impossibility of obtaining exact analytical solutions for real systems, combined with the difficulty of numerically simulating systems with a realistic number of degrees of freedom. If until a few years ago the search for approximate analytical solutions was the guiding thread of many formal developments in this field, currently the computing power achieved thanks to High Performance Computing makes the numerical approach increasingly promising.

Abstract

Ensembles of identical quantum particles have statistical properties that deviate from the classical Boltzmann distribution. Quantum statistics drastically depend on the constituent particles being bosons or fermions, with tangible consequences on the properties of low-temperature quantum gases. We briefly review the properties of quantum statistics with some of their most spectacular consequences. The additional interaction between the particles enriches enormously the panorama leading to a huge variety of phenomena, two examples are magnetism or superconductivity.

Key points

- The statistical properties of ensembles of indistinguishable particles drastically depend on their nature, being bosonic or fermionic. Bose-Einstein condensation, the specific heat of solid at low temperatures, are only few important examples of the relevance of quantum statistics.
- The interplay of quantum effects and interactions in systems of many particles is at the heart of a multitude of macroscopic phenomena, ferromagnetism or superconductivity are only two examples of this sort.
- Phase transitions can occur also at zero temperature, driven by quantum fluctuations.

Introduction

One of the fundamental results in classical statistical mechanics is the Boltzmann distribution function (Huang, 1987). Given a system formed by a large number of identical particles and in contact with a thermal reservoir, it gives the probability for the system to have a given energy E . The Boltzmann distribution can be derived by counting the number of possible microscopic configurations which lead to the same energy and assuming that they occur with the same probability. Another crucial assumption, which seems perfectly justified in the classical world, is that the particles, albeit identical, are supposed to be distinguishable. This last hypothesis does not hold in the quantum world, as one of the postulates of quantum mechanics states that identical particles should be considered as indistinguishable (Eisberg and Resnick, 1985). The wave function of a system of identical particles should be unchanged, up to a phase factor, under a permutation of two of them. The standard argument to derive the statistics is to apply a permutation between two particles twice, that is, restoring the initial configuration. It immediately follows (the 2D case is not considered) that under a permutation, the wave function can remain unchanged (symmetric) or change sign (antisymmetric). These two cases define two different classes of particles named bosons and fermions, respectively. Bosons are particles with an integer spin, while for fermions, the spin assumes half-integer values. In both cases, the presence of a particle in a given state influences the probability of the other particles to be in that state; this is not the case in the hypothesis which leads to the Boltzmann distribution. Indistinguishability of identical particles and then quantum mechanical effects are intimately related to the fact that the wave functions of two particles have appreciable overlap. Decreasing the temperature T or increasing the density, ρ , of an identical particle system will lead to a wave packet overlap when the thermal de Broglie wavelength $\lambda_{dB}(T) = \sqrt{2\pi\hbar^2/mk_B T}$ becomes of the order or greater than the average distance between particles, $\lambda_{dB}(T) \gtrsim d \approx 1/\rho^{1/3}$. If P_1 is the probability of adding a classical particle to a state with n particles, from the symmetry properties of the wave functions, it is easy to show that in the case of fermions or bosons, this probability is respectively suppressed by a factor $(1 - n)$, or enhanced by a factor $(1 + n)$. The probability for two bosons to be in the same quantum state is enhanced; on the contrary, fermions obey the Pauli principle which forbids two fermionic particles to have the same quantum numbers.

In order to obtain the distribution function for fermions and bosons one can proceed as follows. Consider two energy states E_1 and E_2 ; the principle of detailed balance states that in equilibrium the ratio of transition rates between the two states is equal to the ratio of the populations of particles in the two states or, equivalently, to the ratio of the Boltzmann factors: $\Gamma_{2 \rightarrow 1}/\Gamma_{1 \rightarrow 2} = n_1/n_2 = e^{-\beta(E_1 - E_2)}$. The probability of having n fermions/bosons in a given state can be expressed in terms of the Boltzmann distribution if the rates are properly modified so as to account for the suppression/enhancement factor due to the occupancy of the final state. The detailed balance condition can then be rewritten as $n_1(1 \pm n_1)/[n_2(1 \pm n_2)] = e^{-\beta(E_1 - E_2)}$ where $\beta = 1/k_B T$, T is the temperature and k_B is the Boltzmann constant. From the previous equation it follows that the distribution functions for quantum particles are

$$n_{FD}(E) = \frac{1}{e^{\beta(E-\mu)} + 1} \quad \text{for fermions} \quad (1)$$

$$n_{BE}(E) = \frac{1}{e^{\beta(E-\mu)} - 1} \quad \text{for bosons} \quad (2)$$

In the previous equations the chemical potential μ fixes the average total number of particles. The functions $n(E)$ are named after the scientists who formulated them, as Bose–Einstein and Fermi–Dirac distribution functions. Eqs. (1) and (2) are represented in Fig. 1 for different values of the temperatures. At energies E much larger than $1/\beta$, the quantum statistics approaches the Boltzmann distribution; in the limit of high temperatures, the average occupation of each energy state is much smaller than one and the quantum effects can be ignored. Indeed for $n \ll 1$, the suppression/enhancement factor related to the quantum statistics can be ignored and thus the classical distribution function is recovered. In the low temperature limit, the quantum effects become dominant. Bose–Einstein statistics lies always above the Boltzmann distribution. The Fermi–Dirac distribution function is always less than one (due to the Pauli principle), and at zero temperature, drops abruptly from one to zero at the (so-called) Fermi energy E_F (coincident in this case with the chemical potential).

The differences in the distribution functions will reflect in the properties of Fermi and Bose systems at low temperatures. Although it is impossible to briefly review this huge field of investigation, it is nevertheless useful to recall a few brief important examples where quantum statistics plays a dominant role. In order to keep the presentation as simple as possible, perfect gases are considered, that is, the only contribution to the energy is due to the kinetic term while interaction between particles are disregarded. The fact that a direct interaction term is not present does not mean that the particles do not feel each other. As discussed already, indistinguishability implies that the probability for a particle to occupy a given state influences the probability of the other particles being in the same state. Let fermions be considered first. At zero temperature, from the Pauli principle, it follows that all states below a certain energy are occupied while all the states above it are empty. The energy of the highest occupied level is defined as the Fermi energy. A Fermi gas is said to be degenerate when its temperature is small compared to E_F/k_B ; in the opposite limit of a non-degenerate gas, the properties are those of a classical gas and therefore, they are not discussed here. For a gas of N fermions contained in a volume V , the Fermi energy is given by

$$E_F = \frac{\hbar^2}{2m} \left(\frac{3\pi^2 N}{V} \right)^{2/3} \quad (3)$$

Fig. 1 The Fermi–Dirac distribution function (thin solid curve) is compared to the Boltzmann distribution (dashed-dotted curve) for a temperature of $T = 0.2 \mu/k_B$. The agreement with the classical distribution is good only for energies far above the Fermi energy. At low energies the Pauli principle prevents the double occupancy of the same state as it would follow from the classical analysis. For completeness, the Fermi–Dirac distribution is plotted also at lower temperature $T = 0.01 \mu/k_B$; it can be noted that it approaches a step function at zero temperature.

where $\hbar$ is the Planck constant divided by 2π , and m is the fermion mass. Another useful quantity to characterize the system is the density of states $N(\varepsilon)$, defined as the number of states which are present in an energy shell between E and $E + dE$. For a Fermi gas, counting the states in the given shell results in a density of states

$$N(E) = \frac{V}{2\pi^2} \left(\frac{2m}{\hbar^2} \right)^{3/2} E^{1/2} \quad (4)$$

The chemical potential μ coincides with the Fermi energy at zero temperatures; on increasing T , it decreases and becomes negative (a 3D system is considered) at temperatures of the order of the Fermi temperature $T_F = E_F/k_B$. Typical values of the Fermi energy for metals are such that at room temperature the ratio T/T_F is of the order of 10^{-2} . In this case, which is the most frequently encountered situation, the density of states can be assumed to be constant in an interval of the order of T centered in T_F . A good example to see deviations in the thermodynamic quantities due to quantum effects is to consider the heat capacity of a Fermi gas, such as electrons in a metal. One can recall the equipartition theorem which states that, for a monoatomic gas the heat capacity is constant and is $3/2$. That is what is expected for a Fermi gas at temperatures higher than the Fermi temperature. In the low temperature limit, the only states which contribute to the heat capacity are those in a strip of width $k_B T$ around the Fermi energy, that is, those in the energy region where the Fermi function is smeared. All the other electrons are effectively frozen due to the Pauli principle. The number of electrons thus contributing to the temperature dependence of the internal energy are of the order of NT/T_F , each of them having an energy of the order of $k_B T$. A detailed calculation leads to the result $C_e = (\pi^2/2) N k_B T/T_F$; it goes to zero linearly with temperature. It is possible to measure the electronic contribution to the heat capacity in metals at low temperature (typically of the order of kelvin) when the lattice contribution (which depends on T^3) can be disregarded. Another interesting example of the consequence of the Pauli principle in the thermodynamic quantities is the Pauli spin susceptibility, which measures the spin response of the electron system to an applied magnetic field. Using the same line of reasoning as before, it is evident that at low-temperature spin susceptibility, $\chi = N(E_F)$. Indeed the argument goes as follows: the number of spins which can be flipped by an applied magnetic field is a fraction of T/T_F around the Fermi energy because, due to the Pauli exclusion principle, the other spins cannot be flipped since the corresponding (spin-flipped) state is occupied. The susceptibility per spin is given by the Curie law $\sim 1/T$. From here it therefore follows that the Pauli result of a spin susceptibility is independent of temperature and proportional to the density of states at the Fermi energy. In the presence of electron-electron interaction and/or external potential, instead of the particles, one can describe the properties of the Fermi liquid by means of the long-lived quasiparticle excitations close to the Fermi energy (Abrikosov et al., 1975). The leading temperature dependence of the various observables is not modified (for example the heat capacity remains linear in the temperature dependence); however, the effect of the interaction enters in the renormalization of the parameters characterizing the Fermi liquid. Degenerate Fermi systems are observed in a variety of very different physical situations ranging from electrons in metals to electrons in white dwarfs. It is worth stressing at this point that the effect of interaction between electrons, or interaction of the electrons with the ions of the lattice does not always result in the renormalization of the parameters (such as effective mass).

A completely different behavior is observed in a gas of bosons at low temperatures. Here there is no Pauli blocking; on the other hand, for bosons, the probability of being in the same quantum state is enhanced as compared to the classical value. A very interesting phenomenon observed in the Bose system is that of the Bose–Einstein condensation. Below a given critical temperature, there is a macroscopic fraction of the particles which condense into the state with the lowest energy. In order to grasp the process of Bose–Einstein condensation, it is useful to understand the behavior of the chemical potential close to the transition temperature. (If the total number of bosons is not conserved, as for photons, the chemical potential is zero and the Bose–Einstein distribution coincides with the Planck distribution for the blackbody radiation.) As in the case of fermions, an ideal boson gas with a macroscopic fixed number N of particles of spin zero is considered. The density of states $N(E)$ of this system is given by Eq. (4). The factor $1/2$ is due to the fact that the density of states per spin species is being considered. In order to avoid that some occupation number could be negative, the value of chemical potential must always be less than the ground-state energy which, for simple reasons is assumed to be equal to zero, $\mu < 0$ (see Eq. 2). The chemical potential depends on the number of particles and on the temperature. At zero temperature all the N particles are in the ground state; from this fact it is easy to show that for $T \rightarrow 0$, the chemical potential tends to the ground-state energy as $\mu = -k_B T/N$. The particles are distributed among the ground state and all the excited states as

$$\begin{aligned} N &= \sum_i \frac{1}{e^{(E_i - \mu)/k_B T} - 1} = N_0(T) + \int_0^\infty N(E) \frac{1}{e^{(E - \mu)/k_B T} - 1} dE \\ &= N_0(T) + N_{ex}(T) \end{aligned} \quad (5)$$

The integral in Eq. (5) can be calculated and the result is

$$N = N_0(T) + \frac{V}{\lambda_{dB}^3(T)} g_{3/2}(e^{\mu/k_B T}) \quad (6)$$

where $g_\eta(z) = \sum_{t=1}^\infty z^t/t^\eta$.

At “high” temperature the value $N_{ex}(T)$ is of the same order of magnitude of N , and the population is distributed over all the states, each state being weakly occupied. Below a critical temperature $T_c \propto \rho^{2/3}$, where ρ is the particle density, the ground state becomes macroscopically occupied and the fraction of particle in the ground state is

$$\frac{N_0(T)}{N} = 1 - \left(\frac{T}{T_c}\right)^{3/2} \quad (7)$$

The temperature T_c is the Einstein condensation temperature and satisfies the relation $N_{\text{ex}}(T_c) = N$; it is important to note that the critical temperature is usually several orders of magnitude higher than the level spacing between the ground state and the first excited state. The occurrence of a single quantum state macroscopically occupied is the key to the Bose–Einstein condensation. The experimental observation of Bose–Einstein has been recently realized with dilute alkali gases (Dalfvo et al., 1999).

Quantum statistical mechanics embraces a large class of situations where quantum effects do not necessarily stem from the quantum statistics of the constituent particles. There are a large number of situations where, though the particles are localized (therefore, the indistinguishability is not important), quantum mechanics plays a crucial role. Probably, among the most popular situations, the studies on localized spins interacting through an exchange coupling are mentioned. In this case, quantum effects emerge due to the quantum nature of the spin degree of freedom. The fact that different components of the spin do not commute reflects in a kind of quantum frustration. The impact of spin models in quantum statistical mechanics is not confined only to the theory of magnetism. More generally, pseudo-spin models should be considered as they cover a wider range of materials, for example, glasses and superconductors. They can be described in terms of fictitious spins located in a given network, in certain limits.

As it is already hinted in the previous paragraph, interaction between the particles is responsible for a huge variety of phenomena which will appear in many articles in this encyclopedia. In the brief description made of the properties of Fermi systems, it is mentioned that electron–electron interaction can be incorporated by means of renormalization of the physical parameters characterizing the fermion liquid. However, this is not always the case. Among the others, interaction between particles often leads to instabilities and consequently a phase transition to a condensed phase occurs (Goldenfeld, 1992). Examples of phase transitions are ferromagnetism, superconductivity, and charge/spin density waves, just to mention a few important cases. Phase transitions can be driven both by thermal fluctuations and by quantum fluctuations. In the former case, below a certain temperature the system orders spontaneously even in the absence of any applied field. The prototype example is the ferromagnetic transition; below the Curie temperature, the system will present a spontaneous magnetization even in the absence of any external magnetic field (Yosida, 1998). A quantum phase transition instead takes place at zero temperature, and it is driven by the changing of some parameter, for example, a coupling constant or an external field, of the system (Sachdev, 2000). In this case the thermodynamical properties, for example, the magnetization, are deeply connected to the dynamical ones since both derive from the quantum dynamics of the many-body system. Probably, the simplest example of a quantum phase transition can be described in a model of spin interacting via an (ferromagnetic) exchange coupling (with strong anisotropy in the x -direction) J_x and subjected to an external magnetic field B (say along the z -direction). This model Hamiltonian, known as Ising model in a transverse field, appropriate for this model is

$$H = -\frac{J_x}{2} \sum_{\langle ij \rangle} \sigma_i^x \sigma_j^x - B \sum_i \sigma_i^z \quad (8)$$

where σ^a are the Pauli matrices ($a = x, y, z$). The interaction, in order to give an example, is chosen to be between nearest neighbors. In the limit of a large external field the spin will align along the z -direction. However, because of the quantum nature of the spin degree of freedom, the alignment along the direction of the external field prevents any kind of ordering along the x -direction due to the exchange interaction. By increasing the ratio between J_x/B , at a given critical value the spin will prefer to order along the x -direction, and the system will develop a nonzero magnetization along the x -direction. The transition to the ordered state can be induced at zero temperature solely by the variation of the parameter J_x/B and, as has already been said, is intimately related to the quantum properties of the spin. All the signals for the emergence of a phase transition are contained in the dynamical properties of the interacting spins. If the spins of the Ising model are arranged in a chain, this is one of the few exactly solvable models in quantum statistical mechanics. Here the case of a 3D lattice is considered and the quantum phase transition by means of the mean field approximation is discussed. It consists in replacing the interaction among the neighboring spins by an effective field which acts on each spin, that is, it consists in replacing of $\sigma_i^x = \langle \sigma_i^x \rangle + (\sigma_i^x - \langle \sigma_i^x \rangle)$, where the angular brackets $\langle \dots \rangle$ mean the quantum statistical average, disregarding the quadratic fluctuations around the average internal field. The value of $\langle \sigma^x \rangle$ is determined self-consistently by imposing that the average value of the magnetization calculated with the approximated form of the Hamiltonian, which reads $H_{\text{MF}} = - (J_x z \langle \sigma^x \rangle / 2) \sum_i \sigma_i^x - B \sum_i \sigma_i^z$ of, coincides with the mean field. In the previous equation, z is the number of nearest neighbors. This condition leads to the self-consistent equation

$$\langle \sigma^x \rangle = \langle \psi_{\text{MF}} | \sigma^x | \psi_{\text{MF}} \rangle \quad (9)$$

where the $|\psi_{\text{MF}}\rangle$ is the ground-state wave function of the mean field Hamiltonian (only the case of zero temperature is considered). A numerical solution of Eq. (9) sketched in Fig. 2, shows the behavior that is briefly outlined. As it is beautifully described by Nielsen and Chuang in 2000 (Nielsen and Chuang, 2000), thanks to universality, most of the properties of a system close to a phase transition do not depend on the microscopic details of the model. For the example discussed, while the value of the critical field is indeed dependent on the exchange coupling, the behavior of the magnetization is only related to the dimensionality of the system and to the symmetry which is spontaneously broken.

As it should emerge from these remarks, quantum mechanics plays a different role in classical and quantum phase transitions. Let superconductivity as an example be taken in order to elucidate this point. A transition to the superconducting state is induced by the condensation of a pair of electrons (the Cooper pairs). The effective electron–electron attractive interaction (which in

Fig. 2 A sketch of the magnetization, at zero temperature, along the x -axis is plotted against the ratio B/J_x . The spontaneous magnetization is different from zero only at sufficiently low fields. Close to the critical point the magnetization goes as $|\lambda - \lambda_c|^\beta$. In the mean field analysis discussed in the text $\beta = 1/2$.

conventional superconductors is mediated by the phonons) is responsible for the formation of the pairs. The formation of a bound state of two electrons is a Fermi surface effect, which relies on quantum mechanics. Although quantum mechanical effects are responsible for the instability to the superconducting state, the properties of the transition itself can be described by classical statistical mechanics. In a quantum phase transition, instead, the quantum fluctuations are primarily responsible for the transition itself, which is now related to a modification of the ground-state wave function.

This last paragraph represents a return to the theme in the introduction and a slight deviation from the traditional quantum statistical mechanics. The question of indistinguishability viewed from a different perspective, has stimulated a number of works in the newly born field of quantum information. The (anti-)symmetrized form of the wave function for a system composed by N (fermions) bosons implies that the many-body state cannot be written, even in the absence of any interaction, as a product of wave functions related to each single particle. The many-body wave function is said to be entangled (Vedral, 2003). Entanglement is the property of quantum states to exhibit correlation which cannot be accounted for by classical physics. It arises as a consequence of the principle of superposition in the presence of a Hilbert space with a tensor product structure. Entanglement denotes the nonlocal correlations that exist, even in the absence of direct interaction, between two (spatially separated) parts of a given quantum system. Since the early days of quantum mechanics, understanding the phenomenon of entanglement has been central to the understanding of the foundations of quantum theory. Besides its fundamental importance, a great deal of interest has been brought forth by its role in quantum information. Entanglement is believed to be the main ingredient of computational speed-up in quantum information protocols. In the case being discussed here, entanglement is of statistical origin. With the development of information theory, a great deal of attention has been devoted to the characterization and quantification of entanglement contained in a given quantum state. Although the progress has been impressive, a full characterization is still far from being completed. Parallel to understanding entanglement in systems of two-level systems (qubits) used for quantum information, research has touched the question on how to characterize entanglement in “traditional” condensed matter systems with the aim of finding a bridge between information science and condensed matter (Osterloh et al., 2002).

Conclusion

In order to understand more deeply the role of quantum mechanics in the collective properties of quantum many-body systems, probably conventional approaches in quantum statistical mechanics can be conveniently supplemented by the use of a variety of techniques developed in quantum information theory. As a final example, the attention devoted recently to the study of quantum phase transitions from a “quantum information” point of view is mentioned (Vidal et al., 2003; Osborne and Nielsen, 2002). Both classical and quantum phase transitions can indeed be formulated in the framework of Ginzburg–Landau approach. A crucial point that determines all the properties close to the transition is the fact that the systems behave cooperatively. Classical correlations between particles do not, however, imply that quantum correlations (entanglement) do follow the same behavior. As entanglement is one of the major resources in quantum computation, it is certainly important to be able to understand the properties and the amount of entanglement possessed by a large number of particles close to a quantum phase transition. The link between statistical mechanics and quantum information theory has been carried ahead in refining established methods for examining many-body interacting systems. An QJ; example is the entanglement preserving Density Matrix Renormalization Group, where a deep understanding of the entanglement properties of the many-body systems has helped in reformulating and generalizing this method Daley (Daley et al., 2004). A final mention is made of the attention which is being devoted to the possibility of using quantum spin networks, a traditional arena for quantum statistical mechanics, as quantum channels for transporting and/or manipulating quantum information.

Abstract

This is an overview of the field of quantum biology, focusing on the examples of light harvesting in photosynthesis and radical-pair-based avian magnetoreception. We briefly describe the history and motivation behind categorizing certain biological phenomenon as “quantum” in nature, and explain how these examples might satisfy this criterion.

Key points

- Define what we mean by “quantum” biology, particularly with regard to function and advantage.
- Describe photosynthesis in its basic form, and evidence for and against quantum coherence being important.
- Describe radical-pair-based magnetoreception, why it is classified as quantum, and the latest results in this field.

Introduction

The topic of quantum biology (Lambert et al., 2013a; Mohseni et al., 2014; Scholes et al., 2017; Cao et al., 2020) describes a broad range of potential biological phenomena which may rely on quantum effects to function. While the modern conception of quantum biology arose alongside the demonstration of electronic coherence in light-harvesting complexes in the early part of this century, its history extends back to early speculation by Erwin Schrödinger in his textbook “What is life?” (Schrödinger, 1944), and extensive work by the physical chemistry community in the latter half of the 20th century.

Despite this long pedigree, and immense attention from both the scientific and popular science communities, the existence of an uncontested and clear demonstration of a biological system whose function relies on quantum mechanics in some nontrivial way is still lacking. In this article we will describe the essential parts of the two primary examples of quantum biological systems, and summarize the latest results and progress in each case.

What is a quantum advantage?

Before considering explicit examples, it is useful to clarify under what circumstances, in terms of time scales and temperatures, we might expect quantum mechanics to be important in some biological process. Then, assuming such circumstances are tenable, we will explain why quantum mechanics may sometimes be advantageous over “classical” theories, and hence why it might fulfill some role in either making some biological function more optimal or enabling some functions that cannot exist classically at all.

The understanding and development of quantum mechanics in the 20th century began, generally speaking, with the problem of understanding atomic structure, and the wave–particle duality of light and matter. It was only at very small length and time scales that quantum mechanics appeared in a clear way, and gave rise to phenomena that could not be described with classical theories. The reason we do not see quantum mechanics at large length and time scales is typically attributed to “decoherence”. In other words, in macroscopic systems, a large number of degrees of freedom interact with each other and eventually “smear out” any local quantum effects, giving rise to the observable classical world.

We can imagine focusing on some small part of a larger system, and asking the question of how that small “quantum system” is affected by the rest, which we call its environment. Under some reasonable assumptions, we expect that, after some time interacting with the environment, that small system will reach thermal equilibrium with said environment and thereafter can be described by a

thermal mixture of quantum states. In a thermal state the interaction with the environment has obscured precisely which quantum state the system is in. Such a mixture can be described with an ensemble of possible quantum states in the form of a density matrix:

$$\rho(t \rightarrow \infty) = \sum_i \frac{e^{-\hbar\omega_i/k_B T}}{Z} |\psi_i\rangle\langle\psi_i| \quad (1)$$

This formula tells us that a certain quantum state $|\psi_i\rangle$ exists, in equilibrium, with probability $e^{-\hbar\omega_i/k_B T}/Z$, where ω_i is that state's energy, $\hbar$ is the reduced Planck's constant, k_B is Boltzmann's constant, T is the temperature, and Z is the partition function which normalizes these probabilities to one. Intuitively, such a thermal state can be considered as becoming classical at high temperatures because it has no coherence between eigenstates of the system ψ_i . Such eigenstates themselves however can, in principle, contain coherence (i.e., superpositions in a different basis). At very high temperatures $\hbar\omega_i \ll k_B T$, even these coherences start to be less relevant (an infinite temperature state has no coherence in any basis), and this "classical mixture" obscures any desirable quantum effects. These features give rise to the rule of thumb that quantum mechanical effects are difficult to observe in hot environments.

This is not the whole story, however, as in nonequilibrium situations, common in chemical and biological processes, this thermal equilibrium does not occur immediately. To quote Schrödinger, "living matter evades the decay to equilibrium" (Schrödinger, 1944). If, for example, the arrival of a photon gives rise to a process like electron transfer between a donor and an acceptor molecule, or the excitation of an electron in a molecule to a higher energy configuration, then it may take some time before this "quantum system" reaches equilibrium. How quickly any quantum effects that may then occur are washed away depends not on the temperature alone, but also on how strongly the surrounding environment affects that state. The spin of an electron, for example, is very weakly interacting with anything around it, and thus quantum coherence and correlations can persist for a long time. This weak interaction is what has given rise to the possibility of magnetoreception in radical pairs, as we will describe later.

If the energy difference between possible states in the biological system is either high enough to avoid thermalization, or the system is slow to reach equilibrium on some biologically relevant timescale, what kind of use might biological systems make of quantum mechanics? Why do we presume it to be useful in the first place? The potential for systems operating according to the laws of quantum mechanics gaining some advantage over equivalent classical ones largely comes from the field of quantum computing, through examples like Grover's search algorithm. More mundanely, superconductivity, lasing, and the transistor all rely on quantum effects in less direct ways, but all together suggest the idea that quantum physics can have functional roles, either to speed up certain processes (as is argued in photosynthesis) or enable them to function at all (as is argued in the radical pair mechanism for magnetoreception).

In quantum computing, any advantage that is gained typically relies on preserving coherence (and entanglement), which is another word for the existence of quantum superposition of multiple possible states in a desired basis or set of possible states (or irreducible correlated coherence between multiple systems). The intuition used in the field of quantum biology is then that if quantum coherence is observed on timescales relevant for some biological process then that coherence may potentially play a functional, and even advantageous, role. In the examples that follow, we will see that while arguments and evidence for such a functional role seem reasonable, unambiguously verifying it remains challenging.

Photosynthesis

Light harvesting in plants, algae, and some bacteria is a complex process involving many individual steps, from light absorption at an antenna complex (a pigment protein complex, made up of chlorophyll molecules which can absorb light, at appropriate frequencies, as electronic excitations), to, eventually, charge transfer at a reaction center, which is used to build up an electromagnetic potential across a cell membrane. This potential is then used, by a later process, to form adenosine triphosphate (ATP) and eventually sugars.

The steps between the absorption of energy by an antenna complex and the charge transfer at a reaction center can be understood in the following way. Initially, an electron in a single chlorophyll molecule is excited to a higher energy state. This molecule is in close proximity to other chlorophyll molecules, with which this excited electron interacts via a Coulomb force. This interaction induces the electron in the first molecule to return to its lower energy state, while an electron in the second molecule is excited (one can imagine, from a fundamental physics point of view, that this interaction is mediated by the emission and absorption of virtual photons). The goal of the complex then is to use this interaction between its constituent molecules to funnel energy toward the reaction center, which typically succeeds because of a downhill gradient in the chlorophyll excitation energies, and with the help of energy dissipation from the environment (largely thought to be harmonic motion of the nuclei within the molecules and the protein structure).

The energies and timescales involved depend on the photosynthetic complex being studied, but in general the transfer of energy from antenna to reaction center takes on the order of 1–100 pico-seconds. The time scale at which excitations are lost due to, for example, an electron in a chlorophyll falling back to its original state is much slower, on the order of nano-seconds, and hence the efficiency, per unit of energy absorbed, of photosynthetic light harvesting is incredibly high (though some energy is inevitably lost in various substeps of the process, like the environmentally assisted downhill motion).

Fig. 1 A cartoon schematic of the Fenna-Matthews-Olson complex and its role in the light-harvesting apparatus of green sulfur bacteria. The FMO complex is a type of pigment-protein complex, which exists as a trimer. Within each part of the trimer there are seven (or potentially eight, according to recent research) Bacterio-Chlorophyll (BChl) molecules, which act as nodes in an energy-transport network. The trimers connect a large light-harvesting antenna, a chlorosome, to reaction centers. On the right we have illustrated how a localized excitation on a single BChl can be seen as hopping through the network in a classical fashion (the arrows indicated the strongest couplings between sites). An alternative orthodox semiclassical picture is of an excitation delocalized across the complex, but which then increases the probability of the excitation being close to the reaction center via a classical rate equation connecting delocalized eigenstates. The quantum picture sits between these two extremes, where the arrival of a semilocalized excitation does not immediately thermalize, but experiences temporal beating, or oscillations, on the same time scale that it takes for the excitation to arrive near the reaction center.

There are two traditional, classical, or semiclassical, pictures of this energy transport process:

- The site picture: In this limit (see Fig. 1), the excitation is localized on a single chromophore, and the motion between chromophores can be described by a classical rate equation. This picture may be valid when there is a large amount of disorder and the interaction with the environment is much stronger than the coupling between chromophores.
- The excitonic picture: In this limit, the excitation is delocalized across multiple pigments and is in, or close to being well described by, one of the eigenstates of the full Hamiltonian (though for larger complexes this seems unlikely, and the delocalization may just be across a few pigments). Any preparation in a state which is not an eigenstate (e.g., a superposition of eigenstates, or an excitation localized on a single chromophore, either because of direct illumination or due to the arrival of an excitation from another complex), very quickly thermalizes into its constituent eigenstates. Then, that mixture evolves toward a thermal mixture of even more eigenstates via an effectively classical rate equation. In this picture, an excitation arriving from the antenna complex will be higher in energy, and follow a downhill path, to arrive in a delocalized state which has a large probability of being in a chromophore near the reaction center. Interestingly, this thermalization and downhill energy flow still, fundamentally, relies on a quantum description of the complex and its interaction with the environment (Cao et al., 2020).

It has been this process of energy transfer that has been studied as a potential example of functional quantum biology (Scholes et al., 2017), for which some evidence suggests neither of the above two standard pictures are sufficient. The broad idea is that the movement of the electronic energy from absorption site, to the reaction center, can, potentially, be more efficient when there is both electronic coherence across multiple chlorophyll molecules (i.e., a delocalization of energy), and a nonnegligible lifetime of coherent oscillations between superpositions (i.e., not the instant thermalization typically assumed in the excitonic picture). Combined with the aforementioned downhill arrangement of eigenenergies, and interaction with the environment, these are expected to give a higher efficiency for the movement of energy to the reaction center.

The first observation of nonnegligible quantum coherent oscillations, persisting for hundreds of femto-seconds, between different excitonic (delocalized) states was in the Fenna-Matthews-Olsen (FMO) complex of green sulfur bacteria (Engel et al., 2007; Cheng and Fleming, 2009; Panitchayangkoon et al., 2010; Collini et al., 2010). The FMO complex is itself a pigment-protein complex, comprising seven Bacterio-Chlorophyll molecules, but it largely acts as a wire, or transport route, between a much larger chlorosome antenna and a reaction center (see Fig. 1). The time for energy to move through a single FMO complex is roughly one pico-second; hence, quantum coherent oscillations persisting for hundreds of femto-seconds would suggest it could influence efficiency of the total light-harvesting process.

Superficially, the energies involved also suggest that such a hypothesis is reasonable. Ambient temperatures of 300 K, using our rule of thumb, correspond to frequencies on the order of 200 cm^{-1} , roughly the same magnitude as the difference between the excitation energies of the FMO complex and their couplings. The question of nonequilibrium dynamics allowing quantum effects to persist for hundreds of femto-seconds then depends on how strongly the electronic degrees of freedom interact with their environment, largely thought to be dominated by the aforementioned vibronic motion of nuclei.

Interestingly, no interaction with the environment at all is not beneficial for light harvesting, because a purely quantum model of the energy transfer, without an energy sink to assist in the downhill motion, would lead to localization of the energy on a few sites. Conversely, very strong interaction with the environment can also lead to localization (from the quantum mechanics perspective this is a type of Zeno effect, where the repeated observation of the location of the excitation by the environment prevents it from

propagating). Intermediate ranges of interaction strength can optimize the efficiency of light harvesting and imply that quantum coherent interactions between the system and environment can occur. In addition, structured resonant modes in the environment may further enhance efficiency (Mourokh and Nori, 2015), and imply a nontrivial quantum role for “quantum environments” in light harvesting. For the electronic coherence oscillations to persist for hundreds of femto-seconds implies the environment sits in this sweet spot.

However, it is important to mention that experimental techniques used to demonstrate coherence in the FMO complex are complex, and conflicting results have been observed in attempts to repeat the observation of coherent oscillations. Recent work has shown that very long-lived oscillations seen in some examples may have arisen because vibronic environment oscillations modulate the energy of the electronic ground state (Duan et al., 2017), and not because of excited state electronic coherence as expected. Data in these newer experiments suggest that at room temperature the electronic excited state coherent oscillations only persist up to sixty femto-seconds.

These works give a different perspective on the role of quantum mechanics in light harvesting, and suggest that the orthodox excitonic model is the correct picture. In that picture, described above, the delocalized nature of the electronic states and the quantum nature of the interaction with the environment are what is important for maximizing the efficiency of the transport of energy in the FMO complex (Cao et al., 2020), but transient quantum coherent beating is unimportant. These results also suggest a more pragmatic approach to studying the role of quantum mechanics in light harvesting: quantum models are needed to accurately describe light harvesting, but it does not necessarily imply nature has evolved some mechanism to protect temporal quantum coherence to more efficiently harvest energy. Ultimately, these conflicting observations may need to be answered with more nuanced experimental approaches. Interestingly, novel approaches to spectroscopic studies of these systems involving quantum-enhanced sensing are being investigated (Scholes et al., 2017) as a way to achieve this goal, and artificial photosynthetic mimics of natural systems (Ghosh et al., 2011a, b) are being explored.

Magnetoreception with radical pairs

The mechanism by which some birds and insects navigate has fascinated scientists for decades, suggesting a hidden sense which humans either do not have or cannot access. In most cases, pinning down exactly how this sense functions has been difficult. Behavioral experiments on migratory birds have elaborated several key clues regarding their sensory apparatus (Hore and Mouritsen, 2016), some of which are:

- It acts as an inclination compass. In other words, it does not distinguish north from south, but instead is sensitive to the inclination of the magnetic field lines, which become more steep away from the equator.
- It is sensitive to the presence of certain frequencies of light, and thus might be “photo-activated”.
- It can be disrupted by broadband oscillatory electromagnetic fields.

Interestingly, many of these features can be explained by a chemical reaction process involving electron spin states in radical pairs (Schulten et al., 1978). Early work on the sensitivity of such chemical reactions *in vitro* only saw a response for magnetic fields much larger than the geomagnetic field of 50 μ T. In fact, sensitivity to very small magnetic fields was initially dismissed as impossible because the energy of electronic spin states in such a field is much smaller than the ambient temperature, suggesting any signal would be obscured by thermal effects.

The answer to this mystery of how sensitivity to very small fields might be maintained is, of course, again the transient, nonequilibrium nature of the processes involved, as we will describe below. Very recently experimental evidence was obtained of radical pair chemical reactions being sensitive to magnetic fields on the same order as the geomagnetic field (Kerpel et al., 2019). This observation, combined with recent progress in identifying specific host proteins in the form of certain types of cryptochromes in flavoproteins that occur in the eye of migratory birds (and the demonstration of their sensitivity to magnetic fields *in vitro* (Xu et al., 2021)) has put radical-pair-based magnetoreception back in the spotlight as a reasonable candidate example of quantum biology.

How exactly is this radical-pair-based reaction sensitive to the earth’s magnetic field, and why is it presented as an example of quantum biology in the first place? A radical is a molecule with a single unpaired electron, which can then behave “magnetically” because of the electron’s spin which, in a magnetic field, behaves like a quantized magnetic degree of freedom. Two radicals formed together, a radical pair, have an important property; they can be created in a highly correlated spin state, where the spin of the electron in a single molecule is not well defined (see Fig. 2). Essentially we do not know which spin is aligned up, and which is aligned down, so that they are described by a highly entangled superposition (in the form of a singlet or triplet state).

An important second property is that if this state changes in a certain way, for example, it changes from a singlet to a triplet state, the radical pair relaxes to a different chemical product than if it stayed in its original spin configuration. The logic then is that these two different “products” can give rise to biologically detectable signals, suggesting that if the singlet/triplet ratio depends on the alignment with the earth’s magnetic field, one would have a functioning magnetic compass.

The “quantum” part of this process is largely discussed in terms of the singlet-triplet states and how they are converted from one to the other. To elaborate further, it is useful to consider the schematic diagram in Fig. 2. As mentioned earlier, the initial singlet state of the radicals is that of a superposition of one of the electron spins pointing up, and the other down, for example,

Fig. 2 A cartoon schematic of the radical-pair mechanism for magnetoreception. Certain frequencies of light are thought to set off a process which creates radical pairs in cryptochrome within the eye of certain species. The two unpaired electrons in the radical retain their initial singlet correlation state. In the presence of inhomogeneous nuclear hyperfine interactions and the earth's magnetic field, the singlet state changes, converting into triplet states and back again. The radical can either decay back to its groundstate, when the electrons are in the singlet configuration, or into a different transient product, when they are in the triplet configuration. This is an irreversible process which is thought to lead to a biologically detectable signal. The ratio of singlet-triplet products depends on the angle of the external field, and may eventually give rise to a visual cue. (Here, a European robin, shown in a photo used in a modified form under creative commons licence v4.0 <https://creativecommons.org/licenses/by/4.0/> from Alexis @ <https://www.inaturalist.org/photos/30476121g>)

$\psi_S = \frac{1}{\sqrt{2}}(|\uparrow\downarrow\rangle - |\downarrow\uparrow\rangle)$. In the presence of both the geomagnetic field and an anisotropic nuclear hyperfine interaction this state will interconvert with the triplet states ($\psi_{T_0} = \frac{1}{\sqrt{2}}(|\uparrow\downarrow\rangle + |\downarrow\uparrow\rangle)$, $\psi_{T_+} = |\uparrow\uparrow\rangle$, $\psi_{T_-} = |\downarrow\downarrow\rangle$).

This interconversion between singlet and triplet states occurs coherently, oscillating back and forth between the possibilities very quickly, and the degree to which this interconversion changes the probability of occupation of a particular state depends on the angle of the external geomagnetic relative to the anisotropic nuclear hyperfine interaction (though other mechanisms have been proposed (Lambert et al., 2013b)). At any given moment, it is possible for the radical pairs to decay, and form reaction products which depend on the spin state, and thus may give rise, as mentioned, to spin-dependent biologically detectable signals. The quantum aspects of this whole process then clearly lie in the highly entangled nature of the spin states, and the fast interconversion between said states.

There are several interesting technical points about this mechanism that connect back to behavioral experiments: (i) The candidate host of the radical pairs, cryptochrome, occurs in the eye, and is photo-activated. (ii) In addition, the expression of these cryptochromes (ErCry4 to be precise) in European robins peaks during migration season. (iii) To be magnetically sensitive, one of the radicals must have an anisotropic nuclear magnetic hyperfine interaction (to create a "local" magnetic field, otherwise both radicals are affected equally by the geomagnetic field, and no single-triplet interconversion can occur). (iv) Theoretical models have shown then that singlet-triplet ratio would be affected by broadband oscillatory magnetic fields, consistent with more of the aforementioned experiments (Leberecht et al., 2022).

While evidence then is increasing that radical pairs may be a viable candidate for the magnetic sensory apparatus, and a clear example of quantum biology, and that cryptochrome is the host of said pairs, there are still many open questions. There are debates regarding exactly which cryptochrome, and which radicals in said cryptochromes, is used to detect the earth's magnetic field (Leberecht et al., 2022; Wiltschko et al., 2021), whether dipolar and exchange interactions have a deleterious effect on the sensitivity (Kattinig et al., 2016), and whether more realistic models of nuclear hyperfine interactions can produce the required levels of sensitivity. If these, and other, open questions and debates can be resolved, it may well be that avian magnetoreception will be the first concrete example of nature taking advantage of quantum physics in a nontrivial manner.

Other contenders

The interest in quantum effects in light harvesting and magnetoreception has spurred a wider effort to reconsider the potential for quantum effects in other biological processes. For example, quantum tunnelling (Gray and Winkler, 2003; Stuchebrukhov, 2003) has been investigated for allowing new, or modifying existing, chemical reactions. In a classical picture, an electron or proton must

overcome a potential energy barrier to transfer from a donor to an acceptor molecule, for example, but in the quantum picture the probability of this occurring can be modified by the chance of the wavefunction tunnelling through the potential barrier.

In a related idea, it has been suggested that the electron tunnelling through odorant molecules might play a role in our sense of smell (Turin, 1996). In the traditional picture, we can distinguish different odorants through their interaction with receptors which are sensitive to their shape. Some experiments suggest, however, that we can distinguish odorants with the same shapes, requiring an extra mechanism in the overall sensing apparatus. The electron tunnelling mechanism relies on interactions with certain vibrational degrees of freedom within the odorant molecule, which potentially provides additional discrimination between odorants. However, contradictory experiments suggest this may not be feasible (Keller and Vosshall, 2004). Similarly, ion channels, used to transport ions across cell membranes (Vaziri and Plenio, 2010), and photoreceptors in the eye (Prokhorenko et al., 2011; Nagy et al., 2006), have been suggested as other biological processes which may be enhanced or made more discriminatory by the use of quantum tunnelling and quantum coherence.

Conclusion

Despite decades of work, a clear and irrefutable example of a biological system functioning with the aid of quantum mechanics in a nontrivial way is still lacking. Most biological processes occur on timescales where quantum effects are expected to be washed away, but the prospect of some fast nonequilibrium contribution of quantum effects is still in the realm of possibility. In photosynthetic light harvesting, while the persistent electronic beating observed in early experiments is contested, it still appears a delocalized quantum model, taking into account the quantum nature of the environment, is necessary for the correct description and understanding of the light-harvesting process. Similarly, for magnetoreception, despite the difficulties in isolating and studying the precise structures and mechanisms hypothesized to form the vital elements of the radical-pair mechanism, evidence is increasing that such a mechanism is at least feasible, and might explain the results obtained from behavioral studies.

Abstract

Quantum mechanics and biology are seldom considered within the same framework because they seemingly belong to well-separated kingdoms. Quantum mechanics is the fundamental theory to describe the infinitesimally small objects, elucidating the physical properties of Nature at the scale of atoms and subatomic particles. Biology is the science of life, devoted to the study of the behavior of living organisms on a macroscopic scale, where the classical mechanics is the supreme ruler.

Quantum objects are small, cold, and well-controlled. Life is complex, disordered, ‘hot and wet.’

Although the impression that quantum mechanics is limited to the microworld governs the general understanding of science, recent experimental and theoretical studies challenge this neat dichotomy and demonstrate that natural macroscopic phenomena like photosynthesis, olfaction, and bird navigation can be investigated remarkably well through quantum mechanical formalisms. This is precisely what is now recognized as ‘quantum biology’: the application of quantum theory to aspects of biology for which classical physics fails to provide an accurate description.

Key points

- Define the research field of Quantum Biology
- Provide a brief historical overview of its developments
- Introduce to the non-experts the concepts of quantum mechanics needed to understand the advances in quantum biology
- Review the main research areas involved in quantum biology research, highlighting open questions, criticalities, and possible developments
- Discuss the latest developments and possible future perspectives

Introduction

Quantum biology is the study of applications of quantum mechanics to fundamental biologically relevant problems. It aims to bridge the apparently uncorrelated realms of quantum mechanics and biology (Arndt et al., 2009; Lambert et al., 2013; Brookes, 2017; Marais et al., 2018; McFadden and Al-Khalili, 2018).

Quantum mechanics is the fundamental theory that describes the microscopic world. It is a powerful tool to describe particles, atoms, and molecules but it gives way to classical physics on the macroscopic scale of sensible world where instead biology, the science of life, operates. Somewhere between molecules and macroscopic world lies a boundary where quantum behavior ends and the familiarity of classical physics begins (Huelga and Plenio, 2013). The impression that quantum mechanics is limited to the microworld permeates the general understanding of science. Yet this partitioning of the world is just a convenient way to simplify the description of the different phenomena and it is but a useful approximation of a world that is quantum at all scales.

Although quantum effects are perhaps harder to see in the macroworld, the reason for that has nothing to do with the size *per se* but with how quantum systems interact with one another. The feature of quantum mechanics that most distinguishes it from classical mechanics is the description of systems in terms of coherent superpositions of distinct physical states. In fact, such superposition states are very fragile in the presence of dissipation and rapidly collapse to a classical mixture exhibiting no unusual interference features. This is the so-called decoherence process. The predictions of quantum mechanics indeed converge to those of

classical mechanics in the macroscopic world when a system moves to higher energies or—equivalently—larger quantum numbers. Larger objects tend to be more susceptible to decoherence than smaller ones, which justifies why biologists can usually get away with disregarding quantum mechanics (Joos and Zeh, 1985).

Strictly speaking, all biochemical compounds are quantum objects in the sense that they are made of atoms bound by quantum-mechanical forces. Therefore, one could claim that all of biology is in fact, a quantum mechanical process. In effect, the definition of quantum biology is more subtle since it is based on the idea of addressing the dynamical nature of biological processes, where a classical description is inadequate. For example, it was recently suggested that a good definition of quantum biology could be provided on the basis of the physical ‘correctness’ of the models used to describe biological processes and the capability of classical versus quantum mechanical approaches to explain their behavior (Marais et al., 2018).

In other words, the fundamental question of quantum biology is whether quantum mechanisms play a specific role in the functions of complex biological systems or if they are unable to maintain a quantum coherent state of sufficient duration to have a significant influence. Going even further, one could also wonder if quantum mechanisms can be suitably engineered in macroscopic artificial systems to steer the performances of artificial devices.

Historical overview

The idea that quantum phenomena may play a crucial role in macroscopic living systems dates back to the origin of quantum mechanics. In 1932, 10 years after being awarded the Nobel Prize, Niels Bohr gave a lecture entitled ‘Light and Life’ at the International Congress on Light Therapy in Copenhagen. In his lecture, he raised the question of whether quantum mechanics could contribute to the description and the scientific understanding of living systems and provided an occasion to reflect on the philosophical significance of developments in quantum theory for the life sciences (Bohr, 1933). This proposition fascinated a young physicist in the audience, Max Delbrück, one of the future fathers of molecular biology and Nobel Prize winner in 1969 for his discoveries in genetics (McKaughan, 2005). The original approach of Delbrück was also influenced by the seminal contribution by a luminary in quantum mechanics, Erwin Schrödinger. In 1944, Schrödinger wrote a book with the unusual title ‘What is life?’ based on a course of public lectures delivered in February 1943, under the auspices of the Dublin Institute for Advanced Studies, where he was Director of Theoretical Physics, at Trinity College, Dublin (Schrödinger, 1944). In this book, where he predicted several of the functional features of DNA, he posed essential questions about the possibility of describing biological phenomena with quantum mechanics.

Just as Bohr, Delbrück, and Schrödinger, other founders of quantum mechanics like Heisenberg and Wigner offered speculations on the topic: building upon their success in explaining the properties of non-living matter, they hoped their theory was powerful enough to justify the peculiar living state of matter too. This was prevalent to such an extent that in the late 1940s and 1950s, it was fashionable to suppose that quantum mechanics or some form of “post-quantum mechanics” held the key to the mystery of life.

It is precisely during those exciting years and in this cultural context that the word ‘quantum biology’ was coined for the first time by physicist Pasqual Jordan (Jordan, 1932).

After this period of initial enthusiasm, discussions on quantum biology have begun to diminish. In 1963, Per-Olov Löwdin proposed proton tunneling, an exquisitely quantum effect, as a possible mechanism for DNA mutation and mentioned this new field called “quantum biology” (Löwdin, 1966). In 1979, Alexander Davydov published what can be considered as the first textbook on quantum biology entitled “Biology and Quantum Mechanics” (Davydov, 1979).

However, it was only in the last two decades that relevant developments in experimental techniques such as ultrafast spectroscopy (Hybl et al., 1998; Collini, 2021), single-molecule spectroscopy (Moerner et al., 2015; Liebel et al., 2018), time-resolved microscopy (Huang et al., 2020) and single-particle imaging (Shashkova and Leake, 2017) allowed investigating the biological dynamics on increasingly small length and time scales. These new techniques captured a variety of processes contributing to the function of the living systems that strongly depend on a delicate interplay between quantum and classical physical effects and gave rise to the real dawn of quantum biology (Ball, 2011).

Elementary concepts of quantum mechanics: coherent superpositions of states, tunneling, and entanglement

The formulation of quantum mechanics proposed by Schrödinger describes the dynamics of microscopic systems through the use of wave mechanics. In this framework, the time evolution of the system is represented by the state vector $|\psi(t)\rangle$, which obeys the time-dependent Schrödinger equation: $i\hbar \frac{\partial |\psi(t)\rangle}{\partial t} = H(t)|\psi(t)\rangle$, where $\hbar$ is the reduced Planck constant and $H(t)$ is the so-called Hamiltonian operator, which accounts for the energy levels of the system and all the interactions taking place within the system (Zettili, 2022).

A particularly fascinating aspect of quantum theory is that, given a set of quantum states $|\psi_i\rangle$ describing the system, linear combinations of these states, $\sum_i a_i |\psi_i\rangle$, also belong to the Hilbert space that contains all the states available to the system. In these superpositions, each normalized orthogonal state $|\psi_i\rangle$ is weighted by the complex number a_i , such that $|a_i|^2$ is the probability of finding the system in that state. It is here that quantum mechanics departs from the classical world. The existence of superposition states in the quantum regime results in uniquely quantum-mechanical properties, which are often counterintuitive, like for example a cat being at the same time dead and alive (Castelvecchi, 2018).

For example, when the system is described by a superposition of two states: $\Psi = a_1 |\psi_1\rangle + a_2 |\psi_2\rangle$, the probability density P oscillates in time as: $P(t) = |\Psi|^2 = |\psi_1|^2 + |\psi_2|^2 + 2|\psi_1\psi_2| \cos[(\omega_2 - \omega_1)t]$ where $\omega_i = E_i/\hbar$, with E_i being the energy associated with the i -th state. We refer to this state of the system that gives rise to this time-dependent oscillation in probability density as a coherent superposition state, or *coherence*. More generally, the oscillation term in the probability expression may also include a time-independent phase factor that arises from the complex expansion coefficients (Tokmakoff, 2020). The measured observables are related to this probability. It is precisely the presence of oscillations in the measured observable that acts as a smoking gun for the existence of quantum coherent mechanisms active during the system dynamics during light-harvesting and energy or charge transport (Collini, 2013).

The probabilistic approach of quantum mechanics also allows understanding another important quantum mechanical concept, the tunneling mechanism. The tunneling effect may be explained in terms of the Heisenberg uncertainty principle: the uncertainty in the exact location of a quantum system allows this system to break rules of classical mechanics and move in space without passing over the potential energy barrier (Zettili, 2022). Indeed, when a particle encounters a potential barrier that is higher than its kinetic energy, it will not be able to pass by any classical mechanism. Quantum mechanics, however, allows it to tunnel through this barrier. The tunneling probability strongly depends on the height, width, and shape of the potential barrier as well as on the particle's mass and kinetic energy. The tunneling of light particles like electrons and protons is rather ubiquitous in biology, especially in relation to enzymatic activity. Indeed, hydrogen transfer reactions and the manipulation of carbon-hydrogen bonds feature prominently in a wide range of biomolecular systems (Das et al., 2020).

When the superposition principle is extended to more than a single object or property, the notion of quantum entanglement is introduced. Quantum entanglement is one of the most important phenomena at the heart of the disparity between classical and quantum physics. It is a primary feature of quantum mechanics that is absent in classical mechanics. In simple terms, quantum entanglement is a special form of correlation between quantum states, such that, given an ensemble of particles, the quantum state of each particle cannot be described independently of the state of the others, including when the particles are separated by a large distance (Brody, 2020). There are several formal definitions and measures of entanglement (Vedral and Plenio, 1998) and this effect has so far been demonstrated for photons, superconducting circuits, nuclear spins in small molecules, spin noise in atomic ensembles, trapped ions, and other systems [see Nielsen and Chuang, 2000 and references therein]. Although these demonstration experiments are typically performed under strictly controlled environmental conditions, often including ultrahigh vacuum and ultralow temperatures, the concept of quantum entanglement has been brought up also in conditions more compatible with living organisms (Fassioi and Olaya-Castro, 2010; D'Acunio, 2022).

Applications

In this section, a brief outline of some of the cases in which quantum effects are thought to assist or enhance a biological function is presented. The discussion begins by describing the observations of quantum coherence (superpositions) at room temperature in excitation energy transport through photosynthetic systems. The latest research about the role this coherence might play in the efficiency of photosynthesis in various photosystems is presented together with a critical view of how this concept has been interpreted in the past two decades of investigations. The second example is the radical-pair model used to describe the magnetoreception sense of some avian species. This model invokes the role of quantum coherence and entanglement of singlet and triplet states during the magnetic compass action. Then, the possible interpretation of the sense of olfaction in terms of phonon-assisted inelastic tunneling and the long-range tunneling of electrons through proteins in redox reactions and enzyme catalysis will be presented. Finally, a recent development broadly classified as quantum biology and dealing with quantum features in entire organisms will be introduced, which is a burning issue for the quantum physics community.

It is important to immediately underline that the effective role of quantum mechanical phenomena in the described biological processes and the possible advantages that they can bring to the organisms in terms of improved functionality is still highly debated and is somewhat controversial. Especially in the last examples, the possibility that a macroscopic cognitive species could respond to quantum effects is fascinating, but caution should be paid in the interpretation of the available experiments because these effects are difficult to study and, in most cases, they remain at the level of speculations.

Light-harvesting in photosynthesis and energy transport

Broadly speaking, any process in which some kind of cellular energy is derived from light can be defined as photosynthetic. Key processes in photosynthesis are the absorption of solar energy by antenna complexes and the efficient transfer of excitation energy to photochemical reaction centers (RCs), where the energy is trapped in the form of a stable charge separation, which eventually is converted to chemical energy through a series of dark reactions (Blankenship, 2008). There is a remarkable variety of organisms carrying out photosynthesis, from the well-known green plants to microscopic forms of life such as algae and photosynthetic bacteria. While the structure of the RCs has mainly been retained across different organisms, a remarkable variety of antenna complexes have been identified from various classes of photosynthetic organisms, showing no apparent correlations in their structural organization or in terms of the pigments they utilize. This seems to suggest different evolutionary patterns for different antennas but also emphasizes the importance of the light-gathering process in general (Collini et al., 2009).

Fig. 1 Schematic of the classical and quantum-coherent wavelike mechanisms of excitation energy transfer. The disks represent the different pigments (chlorophylls or bacteriochlorophylls, for example) in an antenna complex. The photoexcitation initially excites one of the sites (A) and it is then transported across the network of molecules (1 to 3). Once it arrives at site B it can irreversibly enter the reaction center and start a charge-separation process. (A) Classical (Förster) energy transfer; the excitation energy jumps randomly between chromophores dissipating energy at each step. Excitation can be on one chromophore at a time. (B) Quantum-coherent energy transfer; the excitation energy is instantaneously quantum-mechanically shared among several chromophores. The system is described as a 'coherent' superposition.

The mechanism of energy transfer in light-harvesting is, in general, well established and well reproduced by the traditional approach that makes use of Förster resonance energy transfer theory (Olaya-Castro and Scholes, 2011). Förster's theory states that, when two molecules A and B are separated by a distance large compared to their size, their electronic coupling can be represented approximately as a dipole-dipole interaction between electric dipole transition moments. Förster theory holds when the electronic coupling is weak, meaning that it is small compared to the coupling to the environment. In this condition, the energy transfer happens after complete equilibration at the photoexcited state of the donor. In this way, any quantum effect between the donor and acceptor excited states is completely quenched by the interaction with the environment degrees of freedom and the energy transfer among several chromophores can be described as a sequence of 'jumps' (Fig. 1A). The Förster model yields simple exponential dynamics and provides an excellent qualitative fit of the observed population transfer rates for most systems.

However, in recent years many subtle aspects of the process, not accounted for in the traditional treatments, were found to be relevant - quantum coherence being one of them. Such subtleties have forced researchers to change the conventional way of thinking about energy transfer and led to the introduction of substantial changes to this basic model (Scholes, 2011; Collini, 2013; Ball, 2018).

The idea that quantum coherent mechanisms could contribute to the excitation energy transfer in photosynthesis was first proposed in 1938 by Franck and Teller (Franck and Teller, 1938). Rather than describing the energy migration among chromophores as a sequence of energy jumps like in the Förster model, they considered the diffusion of a so-called Frenkel exciton (Frenkel, 1931). When the electronic coupling becomes stronger compared to the interaction with the environment, the so-called "strong coupling" limit is reached, and the excitation energy transfer acquires the quantum-coherent character. In the strong coupling limit, the donor and acceptor electronic states mix strongly to produce new, delocalized states that are little perturbed by the interaction with the environment. Within these states, known indeed as Frenkel excitons, the energy is shared quantum mechanically among several chromophores. This is the so-called wavelike transfer (Fig. 1B) (Collini and Scholes, 2009; Olaya-Castro and Scholes, 2011; Scholes et al., 2014).

For many years, although intrigued by the idea of quantum-driven processes, scientists treated their presence mainly as some kind of academic curiosity, until when new technological advances in spectroscopy allowed recording direct experimental proof of quantum coherent dynamics in natural photosynthetic complexes. The first evidence for coherent mechanisms came through the measure of oscillations in pump-probe signals in the late 1990s (Edington et al., 1995; Savikhin et al., 1997). However, a turning point in the discussion was possible only with the development of two-dimensional electronic spectroscopy (2DES) (Hybl et al., 1998). Thanks to the time and frequency resolution of these techniques, it is possible to directly follow the evolution of quantum coherences in light-harvesting complexes and differentiate Förster-type energy transfer from quantum-coherent mechanisms (Hybl et al., 2001). The presence of cross-peaks in the 2D maps was associated with couplings between exciton states, while their oscillations along the third time dimension were assigned to electronic quantum coherence, i.e., the time evolution of coherent superpositions between exciton states (Collini, 2013, 2021; Branczyk et al., 2014; Gelzinis et al., 2019). In 2007, two-dimensional (2D) electronic spectra recorded at 77 K for the Fenna-Matthews-Olson (FMO) complex isolated from photosynthetic green sulfur bacteria showed a striking quantum beating pattern explained by Engel et al. to arise from long-lived coherent superpositions of electronic states (Engel et al., 2007). In 2009, similar oscillatory signals were revealed for the main light-harvesting complex of higher plants (LHCII) and were interpreted as quantum-coherent energy transfer (Schlau-Cohen et al., 2009). These initial results were obtained at cryogenic temperatures. A few years later, a significant development came when the Engel (Panitchayangkoon et al., 2010) and Scholes (Collini et al., 2010) groups found independently similar coherent oscillations at physiological temperatures in FMO and the light-harvesting complexes of two species of marine cryptophyte algae, respectively. Since then, many photosynthetic pigment-protein complexes extracted from different organisms have been investigated in cryogenic and physiologically relevant conditions (see for example, Lambrev et al., 2020 and references therein).

These findings rejuvenated the long-standing discussion regarding relationships between the energy transfer efficiency and quantum features. In fact, the possibility that quantum coherent dynamics could boost the efficiency of biological light-harvesting

systems and effectively funnel the energy transport has been discussed. Within this framework, it was proposed that coherence could improve robustness against energetic disorder or dynamical perturbations (Mohseni et al., 2008; Plenio and Huelga, 2008), be used as a strategy to overcome energy traps (Akihito and Fleming, 2009) or as a mechanism that may speed up the search for the lowest energy level (Engel et al., 2007). Even more bewildering is the possibility that the practical functionality of quantum coherent phenomena may be connected with the ability of natural systems to modulate their function under different environmental conditions through mechanisms related to quantum entanglement (Fassioli and Olaya-Castro, 2010; Scholes, 2011).

After the initial burst of enthusiasm, the increasing body of experimental observations and theoretical modeling and the growing comprehension of the spectroscopic observables suggested a more cautious approach. The case of FMO, probably the most studied and modeled complex, is a clear example of this trend. After numerous experiments and models both for and against the presence of long-lived electronic coherence, recent 2DES experiments suggested that these long-lived (in the ps time scale) coherences originate mainly from ground state vibrations and not from exciton-exciton superpositions, which decay in a faster timescale (within hundreds of fs) (Duan et al., 2017; Thyryhaug et al., 2018). However, experimental confirmation of excited-state vibronic coherence was also found and its role in excitation energy transfer in photosynthesis remains to be determined. It is thus clear that, despite two decades of investigations, the role of quantum (vibrational, vibronic, or electronic) coherence in light-harvesting remains a highly engaging albeit controversial issue (Christensson et al., 2012; Duan et al., 2017; Scholes et al., 2017; Cao et al., 2020).

There is, however, a general consensus in admitting that 2DES played an essential role in resolving the dynamics and pathways of energy and electron transport in various light-harvesting antenna systems and reaction centers with an unsurpassed level of detail. The investigation on the role of quantum effects in the dynamics of photosynthetic complexes, regardless of whether or not these effects are relevant in Nature, had the merit to trigger important new lines of research. Indeed, it is questionable whether quantum effects can be engineered into artificial systems designed *ad hoc* to control quantum coherent energy or charge transfer (Scholes et al., 2011).

Avian magnetoreception

Avian magnetoreception is a sense which allows some species of migrating birds to detect Earth's magnetic field to perceive direction, altitude, or location. This sense is used for orientation and navigation (Wiltschko and Wiltschko, 2012). It represents the second prominent example (beyond photosynthesis) typically invoked in quantum biology research.

A series of early behavioral experiments have revealed several important details about this sense: (i) it is photoreceptor based (i.e., it depends on the presence of specific frequencies of ambient light); (ii) it is sensitive to changes in the intensity of the external magnetic field and (iii) it is strongly disturbed by magnetic pulses and very weak external oscillating magnetic fields. To account for all these pieces of evidence, more than 40 years ago, Shulten et al. proposed the so-called radical-pair mechanism, graphically summarized in Fig. 2 (Schulten et al., 1978).

Although the exact details can be pretty complex, the process can be summarized in three steps. First, the initial photoexcitation stimulates electron transfer and a radical pair formation. A radical pair is typically a pair of bound molecules, each having an unpaired electron. These pairs are generated via photochemical processes in spin correlated states (i.e., singlets or triplets).

Once formed, the radical pair oscillates between singlet and triplet spin states before a final step of recombination and neural interpretation. When the system is in a singlet-triplet superposition, it experiences the influence of the Earth's magnetic field. Depending on that, different recombination products can be formed, which are biologically detectable. Thus, if the relative weights

Fig. 2 The three main steps of the radical pair mechanism for avian magnetoreception. (1) Light-induced electron transfer from one radical-pair-forming molecule (for example, in a cryptochrome in the retina of a bird) to an acceptor molecule creates a radical pair. (2) The radical pair oscillates between singlet (S) and triplet (T₊, T₋ and T₀) states under the influence of the Zeeman and hyperfine effects. (3) Spin-dependent recombination into the chemical products.

of the singlet and triplet states are sensitive to the angle of the Earth's magnetic field, the reaction products will reflect this sensitivity, leading to a magnetic compass.

The radical pair theory has given rise to numerous papers discussing the role of quantum coherence and entanglement of singlet and triplet states during the magnetic compass action (Zhang et al., 2015). It has been suggested that the incredible accuracy of the avian compass can only be justified as the result of genuinely quantum mechanical effects (Hiscock et al., 2016). However, there remains some doubt about whether the compass mechanism is indeed a quantum phenomenon or can be described using a semi-classical framework.

Olfaction and tunneling

Olfaction, i.e., the sense of smell, is traditionally explained in terms of a shape theory known as the “lock and key” model (Moncrieff, 1949; Amoore, 1963), which states that a particular odor can be smelled when both shapes of the odorant molecule and the corresponding receptor perfectly fit each other. Then, the sense of smell would depend only on the shapes of molecules. The model can be modified by introducing a distortion of the whole system to induce a more appropriate mutual fit (“hand and glove” model). A more refined demonstration of the idea requires that the receptors respond to only one structural feature, such as a functional group, instead of the main body of the odorant (“odotope” model) (Mori and Shepherd, 1994). There is plenty of evidence that supports these shape-based theories. Still, some findings are against them: structurally different odorants that smell similarly and structurally similar odorants that smell differently (Tirandaz et al., 2017).

Based on this observation, a controversial theory, first developed by Dyson in 1927 (Dyson, 1928) and then further developed by Wright (Wright, 1977) and by Turin (Turin, 1996), was proposed. It is based on the idea that the signature of the scent is due to the odorant's unique vibrational spectrum and not to its structure (“swipe card” model). Through fruit fly behavioral experiments, it was observed that molecules with the same shapes correspond to completely different smells (Turin, 1996). To explain this evidence, it was proposed that vibrational modes, different and characteristic for each molecule, play a crucial mediating role in signal transduction. Indeed, a mechanism has been proposed where the presence of a vibrational mode with energy compatible with the difference in energies between two energy levels on the receptor can promote the electron transfer via inelastic electron tunneling, triggering the ensuing odor recognition process. In other words, the signal transduction is described in terms of phonon-assisted inelastic tunneling of an electron from the donor to the acceptor sites of the receptor, mediated by the odorant molecule (Fig. 3). The specificity of the vibrational modes of molecules would guarantee a further level of selectivity to the process with respect to the “lock and key” model. More recently, this model was revised and expanded by Brookes (Brookes et al., 2007) and several arguments have been brought forth both in favor and disfavor of this theory, which still remains highly controversial (Eric et al., 2015; Pandey et al., 2021). Moreover, it should be noted that the vibrational theory of olfaction in principle can also be described using semi-classical approaches (Brookes et al., 2007), and, therefore, it is not clear to what extent this could be effectively considered as a quantum biology phenomenon.

Nonetheless, tunneling is an exquisitely quantum mechanical effect, studied since the dawn of quantum mechanics. Besides the controversial vibrational theory of olfaction, there are several other well-established examples of biological processes relying on long-range particle tunneling. For example, it is well known that electron and proton tunneling plays essential roles in redox reactions and enzyme catalysis, respectively (Gray and Winkler, 2003; Allemann and Scrutton, 2009). Indeed, it has been experimentally demonstrated that long-range electron transfer between redox centers in proteins separated by distances of 1–3 nm is crucial in respiration and photosynthesis (Moser et al., 2010). It is remarkable that such long-distance electron transfer

Fig. 3 Possible role of quantum effects in olfaction. (A) The sense of smell is activated when odorants are absorbed by odorant receptors in the olfactory receptor cells in the nasal cavity. (B) According to the vibrational theory of olfaction, the odorant, which has a characteristic vibrational frequency ω_0 , binds to the olfactory receptor forming an electron-donor-acceptor complex. Electron tunneling from the donor to the acceptor is activated if the vibrational frequency of the odorant molecule matches the energy difference. (C) In this model, each odorant can be simulated as an asymmetric double-well potential $V(q)$, where the minima correspond to the donor and acceptor states. The states can be inter-converted by the quantum tunneling through the barrier V_0 (Tirandaz et al., 2017).

in biology might be enabled by quantum mechanical tunneling, possibly mediated, also in this case, by the action of vibrations (Allemann and Scrutton, 2009; Hay and Scrutton, 2012). However, whether or not the electron-conducting proteins have explicitly evolved for coherent electron tunneling still remains a central open question (Moser et al., 2010; Brookes, 2017).

In summary, quantum tunneling is undoubtedly present in a large number of biological processes, but it is experimentally proven only on the level of small-scale chemical reactions.

Quantum features of entire organisms

While in previous examples, the attention was mainly focused on detecting quantum effects on biological processes at the microscopic level, very recently, experiments concerned with quantum features of entire organisms have been proposed. Building on a systematic body of work revealing wave properties of molecules with growing complexity (Gerlich et al., 2011), Lidzey et al. have devised an experiment to strongly couple living photosynthetic bacteria to light. Under certain assumptions, the results obtained could be interpreted as entanglement between the quantized light and light-sensitive parts of bacteria (Coles et al., 2017). Subsequent experiments involving a multi-cellular eukaryote interacting electrically with quantum bits were performed (Lee et al., 2021). The experimental setup consisted in placing a microscopic eukaryote (a tardigrade) between two superconducting qubits at an ultracold temperature so that entanglement between the tardigrade and its immediate environment was achieved, at least according to the authors' claim. While several other experts question the effective existence of any entanglement in this experiment, it undoubtedly represents a stepping stone to more ambitious goals and further discussions.

Conclusion

Quantum effects have been argued to exist in many biological processes. Although all the biological materials can be considered 'quantum' at the atomic level, the extent to which quantum mechanics may really affect the mechanism, dynamics, and efficiency of biological processes in physiologically relevant conditions has, for many years, mostly remained as a negligible curiosity.

Two prominent landmarks have started changing this opinion. First, the recent development of quantum information theory, revealing that quantum mechanics could, in some situations, do things better than an equivalent classical theory (for example speeding up a computation process). Thus, in the same way, it has been suggested that, for example, quantum transport of energy could be more efficient than classical transport. Second, the possibility to directly detect signatures of the dynamical evolution of such quantum coherences through recently developed spectroscopic techniques, allowing, in principle, the experimental verification of the role of quantum effects in biological processes.

To date, conclusive evidence of that is still lacking, and the presence, role, and even the experimental methods of detection of such quantum effects are under scrutiny and debate. The priority for advancing the field must be the design of novel experiments that directly test the quantum biology hypotheses. Indeed, most quantum biology investigations remain at the level of conjectures because of the number of restrictions and challenges to be overcome to observe and measure even the most straightforward quantum effect. Any conclusion is not possible without solid experimental proofs from complex living organisms. At this stage, the available experimental findings seem to be too conflicting to suggest that quantum mechanics can effectively explain all biological systems. However, there is enough evidence to suggest that this hypothesis is at least plausible.

It is not clear what opportunities may be presented in quantum biology, but it will be fruitful to pursue this idea. For example, it has been suggested that quantum biology might play a critical role in the future of medicine and in developing more efficient and robust innovative quantum technologies for solar energy, communication, and navigation that are fundamental in our everyday lives. Even if proven non-relevant in natural processes, the characterization of the role of quantum effects may result anyway valuable if the underlying principle can be applied regardless of whether biology exploits it.

Abstract

Quantum biology is, most simply, the investigation of quantum effects in biological systems. While all matter is fundamentally quantum, quantum biology focuses on those quantum effects that result in properties of biological scale and relevance. It has long been argued that quantum effects are incompatible with biological systems, due to the likelihood of decoherence. But nature is a surprising and enterprising engineer. In this sense, quantum biology is the study of nature's materials and how they might sustain and enhance quantum effects, even in hot and wet environments. Quantum mechanics was developed in response to seemingly anomalous interactions between light and matter. It seems fitting that a great deal of the progress made in quantum biology in the last few decades has been on the topic of photosynthesis: the interaction of light with living matter. The interaction of electromagnetic radiation with matter is also at the heart of many other topics of quantum biology. This review is a broad overview of the current state of this research. While the underlying quantum effects are often similar—energy and charge transfer, tunnelling, spin dynamics—the biological contexts are varied and continue to grow. These contexts include enzyme catalysis, DNA mutation, receptor binding, photosynthesis, microtubule and mitochondrial function, magnetoreception, regulation of the production of reactive oxygen species, calcium ion storage and release and, potentially, consciousness. While there remain a number of reservations regarding quantum biology, progress made in this regard might further our understanding of both quantum and biological systems. With respect to the latter, advances in understanding biology might also contribute to a better understanding of physiology and the development of new therapeutics. But quantum biology might equally advance our understanding of quantum mechanics, by illustrating what quantum effects could look like in the novel materials out of which living systems are built.

Key points

- What is quantum biology?
- What are nontrivial quantum effects such as tunnelling, coherence, and entanglement?
- In what biological contexts do quantum effects occur?
- In what new biological contexts might quantum effects occur?

Introduction

Of what special interest is quantum biology to the study of condensed matter physics? In quantum biology, much attention is paid to the problem of decoherence, which is the loss of quantum effects such as superposition or entanglement due to interaction between the quantum system and its environment. It is often stated that sustained quantum effects are unlikely to occur in biological systems because of the distinct properties of biological matter: the high physiological temperature, the relative disorder of protein environments. Quantum systems are fragile and biological systems are robust. While this may seem an argument against quantum biology, it is also an argument for why quantum biology is interesting, especially with regard to the study of matter. Nature is a novel materials engineer. Adaptability is a driving principle in biology. This seems evident not only on the scale of organisms but also with respect to the matter that constitutes biological systems. Consider the opsins, for instance. This group of proteins is light-sensitive due to the inclusion of the light-reactive chromophore retinal. While retinal absorbs at a given frequency, this absorption can be tuned by the particular protein it is attached to, allowing nature to repurpose a single chromophore to give us color vision across the visible spectrum (Wang et al., 2014; Hoffmann et al., 2006). In many different contexts, the protein environment seems one of nature's aces. The electronic properties of living matter are uniquely interesting. It has even been suggested that almost all biomolecules belong to a fundamentally new class of disordered conducting material, poised at the critical quantum state between metal and insulator (Vattay et al., 2015). While quantum theory might offer valuable insight into biological systems, the opposite is also true. A better understanding of nature's materials might show us new and surprising ways to control and manipulate quantum systems.

A brief history

Quantum biology is sometimes referred to as an emerging field of research. In reality its concerns are almost as old as quantum mechanics itself (McFadden and Al-Khalili, 2018). Quantum theory was first proposed as a way to explain anomalous interactions between light and matter (Zettili, 2009; Haken and Wolf, 1987). In the context of blackbody radiation, the departure of observed behavior from classical prediction was so extreme as to be called the ultraviolet catastrophe. In response, Planck postulated a minimum quantum of energy. This was followed by Einstein's explanation of the photoelectric effect (Zettili, 2009; Haken and Wolf, 1987). Light, it appeared, behaved as both a wave and a particle, that came to be known as the photon. Reciprocally, de Broglie postulated that matter, conventionally understood as being particulate, can also demonstrate wave-like effects such as interference, which was subsequently observed in the case of electrons. These ideas were later formalized by physicists such as Heisenberg and Schrödinger (Zettili, 2009; Haken and Wolf, 1987). While quantum physics was a response to the interaction of light with inanimate matter, many of its founding figures already expressed interest in what insights it might offer in the context of living systems. In 1944, Schrödinger published the book *What is Life? The Physical Aspect of the Living Cell*, which is often cited as the inspiration for the discovery of DNA (Schrödinger, 1944; Marais et al., 2018). Indeed, the term "quantum biology" was already in use as early as the 1930s, by Pascual Jordan (McFadden and Al-Khalili, 2018). The interaction of light with matter was central to the development of quantum theory. Light is also pivotal in the context of living matter. In 1932, Bohr, another figure central to the consolidation of quantum theory, gave a lecture entitled "Light and Life" (Bohr, 1933; Marais et al., 2018). It is perhaps no surprise then that much of the research in quantum biology is focused on photosynthesis: the interaction of light with biological systems. Indeed, the interaction of electromagnetic radiation with matter is also at the heart of other topics of quantum biology. For the most part, however, these speculations would have to remain theoretical until technology caught up with them.

Non trivial quantum effects

Questions around the quantum nature of biological matter may be as old as quantum theory itself (McFadden and Al-Khalili, 2018). But what is more recent is the distinction that is made between trivial and nontrivial quantum effects in biological systems. All matter obeys the laws of quantum mechanics (Zettili, 2009; Haken and Wolf, 1987; Marais et al., 2018). In this trivial sense, biology can be described as being quantum mechanical in the same way that all matter is quantum mechanical. Nontrivial quantum effects, on the other hand, might be thought of as those quantum processes that give rise to functional outcomes on a biological scale, potentially conferring some evolutionary advantage on the system in question (Marais et al., 2018; Al-Khalili and McFadden, 2014; Mohseni et al., 2013; Lambert et al., 2013). Tunnelling, for instance, is the nonzero probability that a quantum particle will pass through a barrier in a manner that is forbidden by classical physics (Zettili, 2009; Haken and Wolf, 1987). Historically, quantum tunnelling was the first of the so-called nontrivial effects to be proposed and observed in biological systems (McFadden and Al-Khalili, 2018; Löwdin, 1963). In 1963, Löwdin hypothesized that point mutations in DNA might be caused by proton tunnelling (Löwdin, 1963). Shortly afterwards, in 1966, DeVault and Chance observed electron tunnelling in enzymes (DeVault and Chance, 1966). In this review we will examine in more detail the advances made in understanding and identifying tunnelling in biological molecules in the context of both DNA mutation and enzymes as well as a number of other biological phenomena in which it may play a part.

The movement of charged particles such as protons and electrons is also the subject of quantum biology in the context of photosynthesis. Research suggests that photosynthetic networks use quantum coherence to maximize their transport of energy and charge (Engel et al., 2007; Brixner et al., 2005; van Grondelle and Novoderezhkin, 2011; Schlau-Cohen et al., 2009; Panitchayangkoon et al., 2010; Collini et al., 2010). Coherence follows from the wave description of matter, and measures how in phase two

waves are. This phase difference gives rise to interference. In quantum mechanics, the superposition principle allows that for two quantum states describing a system, a linear combination of the two also describes the system (Zettili, 2009; Haken and Wolf, 1987). The coherence then quantifies the relationship between the states in this superposition. In biological terms, this means that energy or charge transport between sites in a photosynthetic network can behave collectively, spread out across sites rather than isolated to a single site. A great deal of experimental effort has been directed toward confirming this coherent transport (Engel et al., 2007; Brixner et al., 2005; van Grondelle and Novoderezhkin, 2011; Schlau-Cohen et al., 2009; Panitchayangkoon et al., 2010; Collini et al., 2010). In 2007, it appeared that long-lived quantum coherence in photosynthetic networks had been experimentally observed (Engel et al., 2007). This remains a matter of debate. We will examine this evidence further as well as outlining the case for energy and charge transfer outside of photosynthetic networks.

Of all the weird effects that quantum mechanics gives rise to, entanglement is possibly the strangest. Entanglement describes the nonclassical correlation between different quantum objects, the extent of which means that they cannot be considered separate systems but must be treated as a single system (Zettili, 2009; Haken and Wolf, 1987). In the biological context, entanglement is often invoked with respect to quantum spin. Spin, or spin angular momentum, describes the quantized response of a physical system, such as an electron or proton, to a magnetic field. While spin correlation and entanglement have been extensively reviewed in the context of avian navigation, there is emerging evidence that magnetic fields have an effect on biological systems in a wider context (Hore and Mouritsen, 2016; Rodgers and Hore, 2009; Cai et al., 2010; Gauger et al., 2011; Pauls et al., 2013). The interaction between spin and molecular chirality is also an important emerging subject in quantum biology, especially given the fact that biological molecules favor certain chiralities (Aiello et al., 2022).

Methods and models

While the founding figures of quantum mechanics speculated on the role that quantum effects might play in living systems, the field would remain mostly theoretical until experimental techniques were developed for the investigation of systems on such small time and length scales. Many of the relevant processes—such as energy transfer—happen on ultrafast timescales such as pico and femtoseconds. For a comparison of timescales relevant to quantum and biological processes, see Table 1. Developments in experimental techniques such as ultrafast spectroscopy, single-molecule spectroscopy, time-resolved microscopy, and single-particle imaging have contributed much to the recent accumulation of research in quantum biology (Marais et al., 2018; Kim et al., 2021). Most of this experimental investigation, however, has been in the context of photosynthetic systems. There has also been some suggestion that more tractable, hybrid or artificial models of these systems would be useful in advancing the field (Kim et al., 2021). It remains to be seen how techniques used fruitfully in investigating coherent energy and charge transfer processes might be applied to other contexts in quantum biology. For investigations into tunnelling, the widely adopted experimental approach is selective deuteration or the exploration of isotope effects, given that tunnelling is strongly dependent on the mass of the tunnelling quantum object. This approach is also used to investigate vibration-assisted tunnelling in olfaction and related phenomena, though caution is noted with respect to the possibility of contaminants skewing the results (Paoli et al., 2017). Direct evidence for radical pairs in avian magnetoreception is lacking, with most of the evidence being behavioral (Rodgers and Hore, 2009). However, a recent experiment has demonstrated autoluminescence in the context of radical pair dynamics, opening a new era in experimental techniques relating to radical pairs (Ikeya and Woodward, 2021).

Theoretically the field is more widely developed. A number of models have been used to describe the dynamics of quantum systems in biological environments. Many of which begin with a simple Hamiltonian describing the charge transport or spin dynamics. Classically, energy transport has been modeled using Förster resonance energy transfer (FRET) theory. Quantum Theoretical frameworks of this transport use a variety of approaches including Redfield theory and the numerically exact hierarchical equations of motion (HEOM) (Kim et al., 2021). In the case of the spin dynamics, the initial density matrix treatment of radical pair reactions initiated by Haberkorn has garnered discussion (Haberkorn, 1976; Tiersch et al., 2012; Kominis, 2015). A number of other open quantum systems approaches have been applied to the problem (Haberkorn, 1976; Tiersch et al., 2012; Kominis, 2015). Open systems approaches have also been applied to proton tunnelling in DNA (Slocombe et al., 2022). In modeling the effects of quantum tunnelling in enzymes, reaction rates following from transition state theory are modified by multiplication with a

Table 1 Timescales for different biological phenomena Rodgers and Hore (2009), Engel (2011), Tegmark (2000), Verpoorte et al. (2008), and Song et al. (2014).

<i>Timescale</i>	<i>Quantum effect</i>	<i>Biological processes</i>
Femto/picoseconds	Coherent transfer	Photosynthetic (microtubule) processes
Microseconds	Radical pair mechanism	Ion channel gating
Milliseconds	Spin effects	Enzyme catalysis, neural firing rates
Seconds to hours	Posner molecule model	Gene expression, protein synthesis, memory

The list of biological processes is not exhaustive but gives some idea of which quantum processes have comparable timescales with which biological processes. This does not mean that the particular quantum effect is necessarily implicated in the functioning of that biological process, only that their timescales overlap. We have included the more general “spin effects” as radical pairs may have up to millisecond lifetimes, while nuclear spins may relax faster than seconds. For biological processes that span many timescales, such as magnetoreception, the timescale of interest would be that of the appropriate chemical reaction and signal transduction.

tunnelling correction factor (Kim et al., 2021). Another theoretical approach widely employed in quantum biology is density functional theory, which is often used to calculate relevant parameters. Finally, a number of theoretical approaches use different measures of coherence—such as relative entropy—or entanglement—such as concurrence or negativity—in order to investigate how quantum a given biological system is (Le and Olaya-Castro, 2020; Player and Hore, 2018; Gauger et al., 2011). This is a very brief overview of the methods and models by which quantum biology is investigated. This review is meant as a broad introduction to the field and not as an exhaustive foray into the physics. For excellent overviews of the field of quantum biology see Al-Khalili and McFadden (2014), Mohseni et al. (2013), Marais et al. (2018), and Lambert et al. (2013). For a more detailed history of quantum biology see McFadden and Al-Khalili (2018). For a recent update at the physical details of the models applied in quantum biology, see Kim et al. (2021).

The biological context

Quantum tunnelling

DNA

It is difficult to overstate the role that deoxyribonucleic acid (DNA) plays in our understanding of biological systems. DNA carries the information by which essential proteins are synthesized. Within DNA, the genes that code for proteins consist of specific strings of the four nucleotides with bases: adenine, thymine, guanine, and cytosine. These bases form pairs—adenine with thymine, guanine with cytosine—that constitute the double helix of DNA (Kim et al., 2021). The specificity of this pairing is essential to DNA replication and protein synthesis. It is integral that each base binds only to its complementary base, despite being exposed to any of the possible bases. While DNA mutation has primarily been attributed to external factors such as radiation, it has also been suggested that structural changes to the base pairs may result in mismatched base-pair binding. This is because the bases can exist in a tautomeric form whose pair geometry mimics that of the correct base pairs (Kim et al., 2021; Slocombe et al., 2021). In 1963 the Swedish physicist Per-Olov Löwdin put forward the theory that proton tunnelling might facilitate DNA mutation due to the fact that tautomerization depends on proton relocation (Löwdin, 1963). Since then, there have been a number of attempts to accurately model these tunnelling effects using mathematical and computational techniques (Kim et al., 2021). Experimental evidence for tunnelling follows the well-established path of kinetic isotope effects involving deuterium substitution. Although the research suggests that there is such an effect, further evidence is necessary for confirmation. While the details of progress made in the field of proton tunnelling in DNA mutation are beyond the scope of this review, see Kim et al. for an excellent review (Kim et al., 2021).

Enzymes

While proton tunnelling is considered the first theoretical instance of tunnelling in biological systems, electron tunnelling was first observed in enzymes. DeVault and Chance observed a temperature-independent electron transfer reaction indicative of quantum tunnelling (DeVault and Chance, 1966). Today the study of tunnelling—both electron and proton—in enzymes is a well-developed field of research. Enzymes are large biological molecules, usually proteins, that are integral to the efficient function of biological systems, catalyzing many essential reactions. The action of enzymes on substrates is conventionally understood through transition state theory. This approach to modeling enzyme action includes an energy barrier between the reactants and products of a chemical reaction. The enzyme is thought to lower the necessary activation energy of a reaction (Kim et al., 2021; Sutcliffe and Scrutton, 2000). Quantum tunnelling offers an alternative mechanism for enzyme catalysis whereby the barrier is passed through rather than over (Zettili, 2009; Kim et al., 2021; Sutcliffe and Scrutton, 2000; Brookes, 2017). The contribution of quantum tunnelling to the reaction rate dominates at lower temperatures, where thermal activation no longer contributes (Sutcliffe and Scrutton, 2000; Kim et al., 2021; Brookes, 2017). It is well established that tunnelling is the mechanism of electron transfer in enzymes (Sutcliffe and Scrutton, 2000; Marcus and Sutin, 1985). For the considerably more massive proton, tunnelling in enzymes has elicited mixed responses. See Kim et al. for an overview of the subject (Kim et al., 2021). The kinetic isotope effect, in which rates of transfer are compared for isotopes, is one of the ways in which proton tunnelling might be measured experimentally. However, the kinetic isotope effect may also play a role in enzyme reactions as modeled by transition state theory. The temperature dependence of the kinetic isotope effect might then offer a way to measure the contribution of tunnelling to the rate acceleration. Pressure might also offer a means to measure tunnelling in enzymes, though the accuracy of its predictions remains to be seen (Kim et al., 2021). What is becoming clearer, however, is the contribution that the protein scaffold or, alternatively, water, might play in tunnelling processes (Klinman and Kohen, 2013; Thompson et al., 2021; Marković et al., 2020).

Receptors

Quantum tunnelling in the context of enzyme catalysis has generated a great deal of research, both theoretical and experimental. The hypothesis that tunnelling might also be implicated in the action of receptor binding and activation has been met with more skepticism, however. At the risk of simplification, receptor binding has conventionally been described as utilizing the “lock-and-key” mechanism, by which shape or conformation is the distinguishing factor for the binding of appropriate ligands to receptors (Tripathi and Bankaitis, 2017). In 1996, Turin, building on an idea by Dyson, proposed an alternative or augmented mechanism for one such set of receptors: olfactory G-protein coupled receptors (GPCRs) (Dyson, 1938; Turin, 1996). The theory is that olfactory receptors are activated by electron tunnelling, facilitated by the matching vibrational mode of the appropriate odorant. The standard way of testing the theory is to examine the effects of selectively deuterated odorants, whose different masses yield different

vibrational spectra. Experiments have demonstrated that fruit flies appear to be able to differentiate these deuterated varieties, though insect olfactory receptors differ from mammalian G-protein-related olfactory receptors and results may not be generalizable (Franco et al., 2011; Horsfield et al., 2017). Lake whitefish and the American cockroach have also demonstrated an ability to differentiate between isotopes of amino acids and pheromones (Hoehn et al., 2015; Hara, 1977; Havens and Meloan, 1995). However, the theory remains a contentious one. In two recent paper, Gehrckens et al. address one of the primary objections to the theory: the lack of evidence for electron transfer in GPCRs. They present results that suggest that electron movement is possible in certain classes of these receptors (Gehrckens et al., 2019, 2021). While the vibrational theory of olfaction remains debatable, there have been attempts to generalize the theory to other classes of GPCR receptors, which include those that mediate neurotransmission. Hoehn et al. focus on the neurotransmitter serotonin and its receptors (Hoehn et al., 2015, 2017). They investigate the vibrational spectra of endogenous and nonendogenous agonists that bind to the serotonin receptor. Their theoretical results show that serotonin shares an inelastic electron tunnelling spectral peak with other agonists that activate the serotonin receptor and that the intensity of this peak can be used to predict the potency of an agonist (Hoehn et al., 2015). These results however are not supported by subsequent experimental investigations (Hoehn et al., 2017). Classification schemes for GPCR binding ligands are well developed due to the fact that GPCRs are important pharmaceutical target. There are a variety of ways to classify molecules as potential ligands. Recent research suggests that vibrational spectra might also be used as a feature in classification, specifically in the case of adenosine and histamine receptor ligands (Chee and Oh, 2013; Chee et al., 2015; Oh, 2012). While there is some experimental evidence for different binding patterns of histamine and its deuterated counterpart, it is far from evident that this is due to tunnelling effects (Kržan et al., 2016). Despite a lack of definitive experimental evidence in support of vibration-assisted tunnelling in GPCR receptors, the idea is an interesting one in the context of quantum biology. There has even been some interest in its application to spike protein binding in the context of the SARS-CoV-2 virus (Adams et al., 2022). In various different contexts—including tunnelling in enzymes as well as energy and charge transfer in photosynthesis—the role of the protein scaffold has been highlighted, in particular the vibrational or phonon character of the protein (Brookes, 2017). It appears that protein vibrations can facilitate charge transfer, for a detailed description of this in the context of photosynthesis, see Cao et al. (2020). This would seem to have implications for protein binding, including those proteins that constitute receptors.

Coherent transfer processes

Photosynthesis

Photosynthesis is the process by which organisms such as plants or bacteria convert energy from the sun into chemical energy. Light is harvested and its energy transferred by membrane-bound chromophore-protein complexes of light-harvesting complexes (LHC) to the reaction center (RC). Here, charge separation occurs and the energy is converted into a membrane potential. This energy and charge transfer is extremely efficient, which has led to the suggestion that there is quantum enhancement of the process. More specifically, it has been suggested that quantum coherence—specifically in the form of excitonic coherence or delocalization—contributes to this efficacy, facilitated by the geometry and coupling strengths of the network of chromophores between which transfer happens (Engel et al., 2007; Brixner et al., 2005; van Grondelle and Novoderezhkin, 2011; Schlau-Cohen et al., 2009; Panitchayangkoon et al., 2010; Collini et al., 2010). Classically this transfer is modeled as discrete hopping between the states of each individual site in the network, as described by FRET theory. Taking coherence into account, wavefunction overlap allows for an excitonic “best path” approach, potentially minimizing the disorder introduced by the protein environment. Theoretical approaches vary according to the specific parameters of the networks and the strength of coupling (Kim et al., 2021). It is important to be clear what is meant by coherence as the term appears often and in varying contexts in quantum biology. For an excellent discussion of what is meant by coherence in the context of photosynthesis see the paper by Cao et al. (2020). Experimental advances such as two-dimensional electronic spectroscopy (2DES) have allowed for more precise resolution of energy dynamics in chromophore networks. Experimentally, the signature of coherent transfer is often taken to the appearance of cross-peaks or quantum beats in the spectrum of a system, which represent the interaction between discrete sites. The Fenna-Matthews-Olson (FMO) complex, found in green sulfur bacteria, is often used as a model system for coherent transfer dynamics. In 2007, oscillating cross-peaks were detected in the FMO complex, suggesting coherence might indeed play a role in transfer processes in photosynthetic systems. The study, by Engel et al., is a landmark one in quantum biology, generating many subsequent studies as well as a great deal of debate as to exactly what the results signified (Engel et al., 2007; Kim et al., 2021). While the role of excitonic coherence in transfer processes remains a matter of debate, the role of vibronic coherence is of growing interest (Policht et al., 2022; Abramavicius and Valkunas, 2016). In contrast to the view that the noisy protein environment hinders energy transfer, the coupling of vibrational modes to energy levels has been suggested to enhance transfer processes. Environment-assisted enhancement effects have been supported by both theoretical and experimental results, with evidence for sustained coherence at physiologically relevant temperatures (Kim et al., 2021; Thyryhaug et al., 2018; Dean et al., 2016; Tiwari et al., 2013). In addition to vibration-assisted transfer, a number of studies have looked at whether the spin environment might enhance or disrupt transfer processes (Marais et al., 2013). Advances in experimental techniques have also led to the synthesis of tractable chromophore-scaffold complexes, which allow for better control of the transfer dynamics (Kim et al., 2021; Proppe et al., 2020; Lee et al., 2019). Progress in this direction could contribute to solar cell improvements and green energy technology, as could a better understanding of design principles employed by natural photosynthetic systems, to maximize the efficiency of energy transfer and charge separation (Romero et al., 2017).

Microtubules

The study of energy and charge transfer in the pigment-protein complexes of photosynthetic systems is by now well developed. These complexes are not unique to photosynthesis however. An emerging topic in quantum biology is the study of other contexts in which chromophores may play a role. In photosynthetic light harvesting complexes, the main chromophore of interest is chlorophyll. Biological systems have a host of other chromophores that absorb at different frequencies. Among these is tryptophan, which absorbs in the ultraviolet part of the spectrum (Celardo et al., 2019). Tryptophan is an essential part of tubulin proteins, which make up cytoskeletal filaments called microtubules. Microtubules are instrumental in many cellular processes, including cell division, motility, and intracellular transport (Hameroff and Penrose, 2014; Meunier and Vernos, 2012). Tubulin and microtubules have been central to the physical realization of theories about quantum consciousness. Penrose and Hameroff's Orchestrated objective reduction (Orch OR) theory posits microtubules as the site of quantum computations that give rise to consciousness. Among other things, the theory calls for collective behavior within microtubules, as envisioned by Fröhlich (Hameroff and Penrose, 2014; Penrose, 1989). Fröhlich condensation has long been of interest in the study of quantum effects in biological systems. Although it is generally maintained that classical Fröhlich regimes dominate in microtubules, arguments have been made for quantum fluctuations in Fröhlich condensates of biological matter (Zhang et al., 2019). As interest in vibrational coherence grows, phonon condensates are likely to offer a rich field of research. Recent experimental work supports that out-of-equilibrium collective oscillations are capable of activating long-range electrodynamic intermolecular forces in biological systems (Lechelon, 2022). Microtubules have also generated interest as a site for coherent energy transfer and the disruption of this transfer by drugs such as anesthetics. Craddock et al. suggest that the tryptophan residues present in the tubulin proteins that constitute microtubules are structurally and functionally capable of supporting the possibility of quantum coherent—particularly excitonic coherence—energy transfer (Craddock et al., 2014a, b). The particular geometry of tryptophan networks in tubulin proteins and microtubule filaments has led researchers to suggest ways in which biological materials might manipulate and amplify light, scaling up nanoscale effects by the collective behavior of the tryptophans. While evidence for superradiance in microtubules has been demonstrated using theoretical modeling and computational simulation, experimental verification is still under way (Celardo et al., 2019). The opposite process, superabsorption, is also a growing field of interest, with some evidence that natural design principles might contribute to the design of quantum technologies that maximize energy storage (Quach et al., 2022). Collective effects in light-matter interactions could also provide a way in which ultraweak endogenous photons might have measurable effects in biological systems.

Mitochondria

The presence of microtubule-based tryptophan networks capable of coherent transfer processes has also led to suggestions that mitochondria could funnel photons to microtubules (Kurian et al., 2017). Mitochondria are often termed the “power stations” of the cell due to the fact that they produce adenosine triphosphate (ATP), the molecule whose energy-rich bonds fuel the majority of cellular processes. It is becoming clear, however, that mitochondria play a pivotal role in signaling processes in the body, regulating signaling molecules such as reactive oxygen species (ROS) (Auten and Davis, 2009; Zorov et al., 2014; Nunn et al., 2016). Mitochondria are thought to be a primary site of endogenous photons, which result from oxidative processes in mitochondrial electron transport chains (Kumar et al., 2016; Cifra and Pospisil, 2014). These electron transport chains shuttle electrons through various complexes toward the aim of creating a proton gradient. In this sense they are similar to electron transport chains in photosynthesis. As such, some of the progress made by quantum biology in the context of photosynthesis and radical pair dynamics might be applied to mitochondria. Tunnelling has been reported in mitochondrial electron transport chains (Nunn et al., 2016; Bennett, 2019; Moser et al., 2006). Mitochondria have also been put forward as a site for the biological light-matter interactions that could underpin the mechanism of therapeutic photobiomodulation (Salehpour et al., 2019; Hamblin, 2018).

Spin dynamics

Spin chemistry

Spin chemistry first emerged as a field of research in the 1960s and 1970s to explain how spin and magnetic fields can change the outcome of chemical reactions. The radical pair mechanism was proposed as a way to explain chemically induced dynamic nuclear polarization (CIDNP) (Steiner and Ulrich, 1989; Hore et al., 2020). Radicals are molecules with unpaired electrons. A radical pair is two such radicals whose electron spins are correlated—which means they are related in a specific physical sense—either in a singlet or triplet state. The interaction of each radical of the pair with magnetic fields can convert the spin state between singlet and triplet. Chemical binding is restricted by the spin state, which means that a magnetic field can change the outcome of a chemical reaction by changing the spin state of the intermediate radical pair. This has come to be known as the radical pair mechanism (Steiner and Ulrich, 1989; Rodgers and Hore, 2009; Hore et al., 2020). Further interest in this mechanism has been generated by the fact that the singlet state, for example, is a maximally entangled state (Cai et al., 2010; Gauger et al., 2011).

Avian navigation

In 1978, following on progress made in the field of spin chemistry, (Schulten et al., 1978) suggested that the radical pair mechanism might be applied to the chemical reactions that occur in biological systems, specifically with respect to the avian compass, allowing birds to orient themselves using the weak geomagnetic field. It is generally accepted that birds do use the earth's magnetic field, in the very least as a partial navigational cue (Mouritsen and Ritz, 2005). The radical pair mechanism of avian magnetoreception is

proposed to be photon-generated. In 2000, Ritz et al. (Ritz et al., 2000) suggested that cryptochromes, flavoprotein photoreceptors that resemble photolyases, were a potential candidate molecule for a radical pair-based compass. Since then, a great deal of research has attempted to narrow down which of the various types of cryptochrome is best suited to the purpose of magnetoreception (Ritz et al., 2010; Pinzon-Rodriguez et al., 2018; Liedvogel and Mouritsen, 2010; Günther et al., 2018; Wiltshcko et al., 2021; Xu et al., 2021). This is one of many open questions, which include the role of the dipole and exchange interactions in the radical spin dynamics (Efimova and Hore, 2008). For the most part, only the effects of the external field—Zeeman effect—and the nuclear spin environment local to each radical—hyperfine effect—are taken into account in the commonly accepted models. Common models also primarily involve the interaction of two radicals, although three radical models have also been proposed to offer novel advantages (Babcock and Kattnig, 2021; Kattnig, 2017). Spin-to-chemical transduction is also up for debate. Spin effects in biological systems are likely widespread, but are also very much dependent on the fact that the appropriate reactions are spin-selective. In avian magnetoreception, it is still not entirely clear how the spin states translate into a signal interpretable to the birds, though some theoretical research suggests the spin-dependent visual modulation (Ritz et al., 2000). Given the ubiquity of radical creation in biological systems, it seems amiss that there are so few robust examples of magnetic field sensitivity in these systems. This may be because a number of conditions must be met in order for the radical pair mechanism to confer meaningful magnetic field sensitive spin selectivity. See the excellent review by Kim et al. for a detailed account of these conditions. The radical pair mechanism of avian navigation is theoretically well-developed. It is also supported by behavioral evidence such as the fact that it is a light-dependent, inclination compass, disrupted by oscillating electromagnetic fields (Rodgers and Hore, 2009; Thalau et al., 2004; Ritz et al., 2009; Engels et al., 2014). However, direct experimental evidence of radical pair-mediated magnetic effects in biological cells is still lacking. A recent experiment by Ikeya and Woodward is thus a pivotal one for the field. They demonstrate that flavin-based autofluorescence in cells is magnetic field sensitive. In particular, it is sensitive to weak magnetic fields, a hallmark of the radical pair mechanism. They explain these results as being due to the formation and spin-selective recombination of radical pairs (Ikeya and Woodward, 2021).

Reactive oxygen species

Despite the conditions laid out in Kim et al., spin-selective chemical reactions remain a fruitful field of study within quantum biology. Indeed, given the possible effects of broadband low-intensity radiofrequency electromagnetic radiation on the avian compass, the radical pair mechanism should be afforded more scrutiny in a wider biological context (Engels et al., 2014); if only to rule out the possibility that background electromagnetic radiation may play a role in disrupting important biological processes. Of growing interest is the role that radical reaction intermediates might play in the chemistry and biology of ROS. Reference to ROS is often made in terms of inflammation in biological systems. The term is used generically to define a wide variety of oxidant molecules. It should also be acknowledged that these molecules have very different properties and biological functions that range from signaling to causing cell damage (Sies et al., 2022). In this context, the radical pair mechanism might give some insight into the possible effects that magnetic fields might have on biological systems that are sensitive to the balance of ROS. Usselman et al. show how yields of ROS in live cells can be changed by radical pair dynamics, in particular coherent singlet-triplet mixing (Usselman et al., 2016, 2014). The signaling properties of ROS have been the subject of recent studies examining the effects of weak magnetic fields on stem cell differentiation (Hack et al., 2021). Van Huizen et al. report that weak magnetic fields alter stem cell proliferation and differentiation by changing ROS levels. The authors discuss the possibility of this being due to the radical pair mechanism. The data also demonstrate how weak magnetic fields can both increase and decrease new tissue formation. This has implications for regenerative medicine as well as the targeting of rapidly proliferating cells, as in the case of cancer (van Huizen et al., 2019). Oxygen radicals have also been implicated in the action of lithium in treating bipolar disorder (Zadeh-Haghighi and Simon, 2021). Following from the observation that lithium isotopes appear to have differing effects on animal behavior, Zadeh-Haghighi and Simon propose that this can be explained through the radical pair mechanism, specifically the role that nuclear spin plays in radical dynamics through the hyperfine effect (Zadeh-Haghighi and Simon, 2021). This is also used to explain the effects that lithium and magnetic fields have on circadian rhythms (Zadeh-Haghighi and Simon, 2022a). A version of this radical pair model has been applied in a number of other biological contexts, such as the differential anesthetic effects of xenon isotopes and microtubule reorganization (Smith et al., 2021; Zadeh-Haghighi and Simon, 2022b). These studies remain theoretical and it is yet to be seen if the radicals in question satisfy the conditions laid out by Kim et al. However, given the importance of radicals in biological systems and the growing ubiquity of environmental electromagnetic fields, the subject seems one that is set to grow in scope.

Phosphorus nuclear spin

Radicals are molecules with unpaired electrons. The radical pair mechanism is the result of correlated electron spins. Might nuclear spin pairs play any similar role in the biological context? Nuclear spin has played a central role advancing our understanding of physiology since the development of magnetic resonance imaging (MRI). A recent hypothesis suggests that nuclear spin may play a role in biological systems in more than only an imaging sense. Fisher hypothesizes that the spin of phosphorus nuclei might become entangled in the hydrolysis of pyrophosphate (Fisher, 2015). This entanglement can be preserved if the phosphates bind with spin-zero calcium ions, forming amorphous calcium phosphate or Posner molecules (Fisher, 2015). Phosphorus nuclei are an ideal qubit due to the fact that spin-half nuclei are only relaxed by interaction with other magnetic fields and not electric fields, due to their lack of quadrupolar moment (Fisher, 2015). Fisher contends that due to the rapid tumbling of Posner molecules in body fluid the spin coherence times could be as long as days (Swift et al., 2017). Furthermore, these long coherence times, coupled with the fact that the entanglement could change Posner binding and free calcium ion production, could give rise to “entangled” neural

activation. In this way, entangled phosphorus might play a role in cognition and even consciousness. Fisher also offers an alternative explanation to the isotope dependence of lithium action. Given that lithium can be incorporated into Posner molecules, the nonzero nuclear spin of the different isotopes could have different effects on the spin dynamics of entangled phosphorus nuclei (Fisher, 2015; Swift et al., 2017; Weingarten et al., 2016). While experimental investigations of the hypothesis are still under way, various questions have been raised. Foremost among these would be whether nuclear spin entanglement plays any role in spin-selective chemical transduction. In Fisher's model, the entanglement-sensitive calcium ion production is particularly dependent on the symmetry of the Posner molecules. Research suggests, however, that Posner molecules might favor asymmetric structures (Agarwal et al., 2021). In such a case, it is unclear how nuclear spin dynamics would result in chemical and biological signaling. The long coherence times have also been debated. Player and Hore estimate that intramolecular dipole interactions would relax the nuclear spin within 37 minutes and likely even less (Player and Hore, 2018). Despite these caveats, the potential for nuclear spin processing in biological systems remains intriguing. In the quest to realize physical qubits for quantum computing, phosphorus nuclear spins have been a main contender, they may play an equally important role in biological computing. Phosphorus is important in many contexts in biological systems, not least of which is phosphorylation (Tony, 2012). There is also a proposal that nuclear spin could play a role in lipid membranes as well (Smolin, 2020). Should it turn out that coherence lifetimes are more likely of the order of seconds, this is still long enough to play a role in many important functions in biological systems.

Chirality

Symmetry and symmetry-breaking play an important role in physics. The same might be said for biology. Chirality is a measure of mirror symmetry, that is, the "handedness" of a molecule is described by its chirality. Molecules can exist as left or right-handed enantiomers that cannot be superimposed onto each other. Life, however, favors specific chiralities over others, a preference that is still not yet understood (Inaki et al., 2016). Enantiomers display distinct biological behaviors. For example, different enantiomers of odorants have different scents (Brenna et al., 2003; Brookes et al., 2009). An understanding of chiral effects in biological systems is also essential in the context of pharmaceuticals, where different enantiomers may have different pharmacological outcomes, as seen with thalidomide (Tokunaga et al., 2018). Chirality has become a topic of interest in quantum biology due to the phenomenon of chiral-induced spin selectivity (CISS). Charge transport through small chiral structures results in spin polarization due to the fact that the direction of movement favors a specific spin polarization (Naaman et al., 2019; Aiello et al., 2022). This has elicited excitement with respect to advancements in quantum technologies, see Naaman et al. and Aiello et al. for excellent, comprehensive reviews. At the same time, the centrality of charge transfer in many of the models of quantum biology means that a better understanding of room-temperature CISS effects could have profound implications for our understanding of biological systems. Aiello et al. outline some of the potential applications of chirality in quantum biology, including the chirality of cytoskeletal filaments and their capacity for superradiant effects. They also suggest a role for chirality in understanding how the immune system functions (Aiello et al., 2022). Intriguing results from Gaitanidis et al. reveal a novel biological signal of spontaneous radio-frequency emission in fruit flies (Gaitanidis et al., 2022). The authors suggest that the signal is due to spin-polarized electron currents undergoing radiative relaxation. Even more interestingly, this signal can be interrupted by the administration of chloroform anesthesia, which the authors consider initial proof that the signals originate in the nervous system (Gaitanidis et al., 2022). This implicates spin currents in the action of anesthetics and thus potentially consciousness, a result that appears to support an earlier study that showed electron spin changes under the effects of anesthetics (Turin et al., 2014). A recent study also suggests that CISS could be responsible for the differential viscosity of lactic acid enantiomers, a result that cannot be explained using classical molecular dynamics (Daplan et al., 2022). And finally, chirality has an effect on interactions between electromagnetic radiation and matter. Given that the interaction of radiation and matter is a primary preoccupation of quantum biology, chirality may feature in this context as well (Yuan et al., 2021).

New (and old) avenues of interest

This review has outlined active research in quantum biology and how this might be expanded to related biological contexts. The underlying quantum systems discussed in this review might also offer further insight across the spectrum of biological interests. Research has suggested that redox activity and proton gradients may have played a role in the origins of living systems (Lane, 2010). At the other end of the spectrum, it has also been suggested that most complex biological system, the brain, might be best understood using quantum theory (Hameroff and Penrose, 2014; Penrose, 1989). In 1989, the Nobel Prize winning physicist, Roger Penrose, suggested that consciousness might only be explained by quantum computations in the brain. His collaborator, anesthesiologist Stuart Hameroff, suggested that microtubules and tubulin proteins could act as biological quantum bits or "qubits" (Hameroff and Penrose, 2014; Penrose, 1989). While the theory remains contentious, the question of whether quantum effects take place in the brain continues to generate research (Adams and Petruccione, 2020). The selectivity of ion channels, central to the efficient function of nerve cells, is still not fully understood. There has been some suggestion that quantum effects may play a role (Kim et al., 2021; Salari et al., 2017). The action and mechanism of anesthetics have also been investigated from various angles in the context of quantum biology (Smith et al., 2021; Turin et al., 2014; Adams and Petruccione, 2020; Craddock et al., 2015). Understanding anesthetics is a measurably material way in which to investigate consciousness. Other chemicals that have an effect on consciousness, such as serotonin and lithium, have also been the subjects of quantum biological research (Hoehn et al., 2015; Zadeh-Haghighi and Simon, 2021, 2022a; Fisher, 2015). In addition to this, the role that quantum effects may play in circadian rhythms and associated mental states, has been investigated (Zadeh-Haghighi and Simon, 2022a). Circadian rhythms or body

clocks are essential in biological systems, with synchronization underlying the efficient function of many biological functions (Patke et al., 2020). Oscillatory dynamics also underpin the brain, although the origin and purpose of these brain waves remains unclear (Skinner, 2012). Re-examining oscillation and synchronization through the lens of quantum mechanics may offer new insights.

In addition to the big philosophical questions—what is life, what is consciousness—which might remain unanswered for some time, quantum biology might also offer practical interventions in the near future. Information gleaned from biological systems might very well be applied to the physiological and medical context as well. Indeed, the history of quantum biology and what might be called quantum physiology, show some close parallels. Bohr's "Light and Life" lecture was given as an address at the opening meeting of the International Congress on Light Therapy (Bohr, 1933). The therapeutic use of light won the Nobel Prize for physiology in 1903, as long ago as the origins of quantum theory (Pernow, 1997). More recently, however, light-matter interaction in the therapeutic context has been gathering impetus in both application and verification (Salehpour et al., 2019; Hamblin, 2018; Pooam et al., 2021). Quantum spin, too, has played an important role in the more recent history of medicine, with the invention of MRI. It now appears that spin might also play a role in the development of new therapies that exploit magnetic fields to control and manipulate signaling molecules in the body (van Huizen et al., 2019; Hack et al., 2021).

Conclusion

This review has been a short introduction to the current state of the field of quantum biology. We have not gone into too much detail with respect to each of the various areas of research. For these details, we hope the suggested reviews as well as the reference list will be instructive. What we did hope to communicate is the expanding scope and possible impact of quantum biology. There are still, no doubt, questions that remain to be answered. Take timescales for instance. How do ultrafast processes translate into effects on biologically relevant timescales? And related to this, how are coherence times preserved in the hot, wet, and disordered biological environment? What coherence times are sufficient for a biologically functional outcome? Despite these questions, however, research in quantum biology continues to reveal the possible ways in which electrons, protons, photons, and phonons play a fundamental role in living systems. Further study in this direction will hopefully shine light on the details of these systems. At the same time, quantum biology may offer insights into our understanding of quantum theory as applied in different materials. If nothing else, quantum biology—the study of quantum effects in biological matter—is an investigation into nature's genius for novel material engineering.

Abstract

The field of protein science is witnessing a revolution in the wake of recent breakthroughs such as the artificial intelligence (AI) system AlphaFold which can predict the three-dimensional structure of almost every globular protein from its protein sequence alone. Inevitably, there is some expectation that structure-prediction modelling approaches based on AI may also learn the physics of protein folding to the extent of predicting folding pathways. Motivated by these advances, we briefly review the thermodynamic, kinetic, and structural aspects governing the folding transition from an unfolded protein chain into its final native structure and discuss directions for future research.

Key points

- Non-expert introduction to protein folding physics
- Physically motivated review integrating classical and recent results
- Discussion of future research directions

Introduction

A protein is a heteropolymer of the 20 naturally occurring amino acids. Proteins can be broadly classified as fibrous or globular, depending on whether they play a functional or structural role in their host organism. A recent quantitative analysis of the proteome of model organism *Saccharomyces cerevisiae* estimates that the number of globular proteins per cell stands between 3 and 5.9×10^5 molecules (Ho et al., 2018). This number is likely higher for human cells (Flamholz et al., 2014).

Globular proteins are the cell's workhorses. They perform a variety of functions, the two most common being binding (binding proteins) and catalysis (enzymes). Proteins are also involved in signal transduction, transportation, regulation of gene expression, and enhancement of signaling efficiency and fidelity through binding to other proteins, and organizing binding partners into a functional unit (scaffold proteins), just to mention a few examples.

Following synthesis in the ribosome a linear polypeptide chain spontaneously self-assembles into a specific three-dimensional, soluble structure termed native structure. The term conformation refers to the spatial arrangement of the proteins atoms and the expression native conformation is often used when referring to the native structure. Sometimes the native structure embeds topological entanglements such as a physical knot (Dabrowski-Tumanski et al., 2018b). Moreover, it frequently involves the association of more than one chain as in the case of hemoglobin, the protein that transports oxygen in the blood, a tetramer formed by four polypeptide chains.

Proteins acquire their native structure through the physical process of protein folding and, if everything goes well, each protein sequence will always reproducibly fold into the same native structure in a biologically relevant timescale. However, errors in protein folding (resulting from mutations or adverse environmental conditions) may culminate in malformed proteins

that expose patches of hydrophobic amino acids and frequently self-associate into insoluble fibrils called amyloids. These malformed proteins are the culprits of a class of debilitating (and sometimes deadly) diseases called conformational disorders. So far, more than 40 conformational disorders have been identified including the well-known Parkinson's and Alzheimer's diseases (Chiti and Dobson, 2006). Correct protein folding is therefore essential for the health and function of living organisms, and a complete understanding of the folding process has a considerably high societal impact since it would provide directions toward the cure of conformational disorders. On the other hand, from a physical (or fundamental) point of view, the comprehension of hierarchical organization, cooperative processes, and self-assembly is not complete without a complete understanding of protein folding.

When thinking about protein folding, the expression *protein-folding problem* often comes to mind (Dill and MacCallum, 2012). The latter is not actually a single problem, but rather encompasses three related questions: (a) the folding code: what balance of interatomic forces dictates the native structure of a given amino acid sequence? (b) the structure-prediction problem: can the protein's native structure be predicted from its amino acid sequence by means of computational methods? and (c) the folding process: what are the mechanisms that make a protein fold so quickly in the microsecond to millisecond timescale? (Or, how can order arise from disorder so fast?)

The challenge of solving protein folding prompted the development of computer technologies (i.e., specific machine architectures and software) that can simulate folding with realistic forcefields in a reasonable amount of time. The state-of-the-art is a machine called Anton (Dror et al., 2011), developed by D.E. Shaw Research, that performs multi-microsecond simulations in a single day for systems with more than 1 million atoms (surpassing the computational speed of commercial machines routinely used in research laboratories by two orders of magnitude) (Shaw et al., 2010).

Recently, a machine learning model called AlphaFold, which uses physical and biological knowledge about protein structure, has been regularly predicting the native structure to near experimental accuracy by taking the protein's amino acid sequence as an input (Jumper et al., 2021). The AlphaFold database (AlphaFold DB) (<https://alphafold.ebi.ac.uk/>) already provides access to over 200 million protein structure predictions, which is three orders of magnitude larger than the number of experimentally solved protein structures deposited in the Protein Data Bank (PDB) over the last 50 years. One can therefore claim that this remarkable breakthrough has already solved the structure-prediction problem. But are these models also learning the physics of protein folding, i.e., of how proteins dynamically fold into their native equilibrium structures as shown by experiments and predicted by simulations? Results reported so far are inconsistent. On the one hand, it has been claimed that AlphaFold has learned an energy potential function, suggesting that efficient machine-learning algorithms can disclose critical information about the physical interactions that ultimately lead to the native structure without being trained to do so (Roney and Ovchinnikov, 2022). However, it has also been shown that AlphaFold is not able to correctly produce folding pathways, providing worse predictions than the protein's chain length, a trivial, sequence-independent classifier of protein folding kinetics (Outeiral et al., 2022). The future will tell us if AlphaFold, and other similarly inspired methodologies, will be able to generate correct protein folding pathways and novel insights on protein folding principles (Chen et al., 2023).

Motivated by these latest advancements, here we summarize the status quo of protein folding physics, which encompasses the understanding of thermodynamics, kinetics and mechanisms underlying the transition of a disordered polypeptide chain into its final native ordered structure (Finkelstein and Galzitskaya, 2004).

The native structure: Hierarchical organization and physical interactions

The native structure is a specific three-dimensional structure that determines the protein's biological function. In cells, proteins are synthesized in a molecular machine called ribosome as linear chains of linked amino acids. There are 20 naturally occurring amino acids.

Each amino acid contains a basic amino group, a carboxylic acid group, a hydrogen atom, and an R-group (or side-chain group), which are all attached to a central carbon atom named alpha carbon, C_{α} . Depending on the structure and chemical properties of the R-groups, amino acids can be broadly classified as hydrophilic or hydrophobic. While the former includes electrically charged groups (acidic or basic groups that bear a full negative or positive charge, respectively), the latter are neutral and relatively non-polar.

Amino acids are linked together by a rigid C-N covalent bond termed peptide bond. The latter involves the carboxyl end of one amino acid and the amino group of the next. The term main chain (or protein backbone) is used to refer to the linked sequence of carbon, nitrogen, and oxygen atoms. The term primary structure is used to describe the linear (i.e., one-dimensional) sequence of amino acids linked together along the polypeptide chain (Fig. 1A). The peptide bond and its four adjacent bonds are coplanar forming an amide plane. Each amide plane can rotate around the C_{α} -C and the C_{α} -N bonds, and these rotations are described by the torsional angles φ and ϕ , respectively. Not all φ - ϕ combinations are possible because of steric clashes between backbone atoms. However, some favorable combinations allow the formation of hydrogen-bond interactions between the carbonyl oxygen and amide nitrogen of the main chain. Hydrogen bonds direct (and stabilize with 2–10 kcal/mol) the local structural arrangement of the polypeptide chain into the so-called elements of secondary structure, the most common being the alpha-helix and the

Fig. 1 Hierarchical structure of proteins. Primary structure (A). The two most common elements of secondary structure: the alpha-helix and the beta-strand displayed in full atomistic detail and in cartoon representation (B). Tertiary structure in cartoon representation (C). Quaternary structure of hemoglobin in cartoon representation (D). Interactions that stabilize protein structure (E).

beta-sheet (Fig. 1B). Hydrophobic interactions between non-polar amino acids drive the packing of secondary structural elements into the formation of the tertiary structure (Fig. 1C). The resulting protein structure exhibits a tightly packed core (the fraction of filled space inside proteins is 74%, i.e., almost the same as the maximum density packing of identical spheres), where the formation of weak van der Waals interactions between the side chains groups is highly optimized through side-chain packing.

Often the native structure coincides with the tertiary structure, but in many proteins it contains two or more polypeptide chains, being classified as a dimer or a higher order oligomer (trimer, tetramer, etc.). This level of structural arrangement is termed quaternary structure (Fig. 1D). It is important to note that in the quaternary structure each chain has its own secondary and tertiary structure. The tertiary and quaternary structure can be stabilized by disulfide bonds (a kind of reversible covalent bond formed between the thiol groups, -SH, of two cysteine amino acids), and salt-bridges (establishing between residues with ionizable side chains such as aspartic acid and histidine) (Darby and Creighton, 1995). Despite all these sources of energetic stability (Fig. 1E) the native state of proteins is only thermodynamically marginally stable (~ 10 kcal) regarding the unfolded state. The origins of marginal stability remain undetermined, but it has been argued that it enables proper function (Taverna and Goldstein, 2002).

When discussing protein structure, the term protein domain refers to a distinct functional and/or structural unit in a protein. A domain is responsible for a specific function or interaction. A domain is self-stabilizing and folds independently of the rest of the chain. A protein that is formed by one domain is termed a single-domain protein. A protein subunit, on the other hand, is a separate polypeptide chain of a protein that assembles with other polypeptide chains to form a protein complex (Wang et al., 2021).

Knotted proteins

Knotted proteins are proteins whose native structure embeds a physical (in opposition to a topological or closed) knot (Fig. 2A). The first knotted protein was reported in 1977 (Richardson, 1977) but it was only in 2000, after the development of efficient knot detection methods and loop closure procedures, that these tangled molecules came into the spotlight (Lua and Grosberg, 2006; Taylor, 2000). The most recent survey of the PDB indicates that there are about 1% of knotted entries (Dabrowski-Tumanski et al., 2018b), and a survey of the AlphaFold DB found that knots are present in 0.2% of the human proteome (Perlinska et al., 2023). Knotted proteins exhibit different levels of topological complexity, depending on the minimal number of crossings of the polypeptide chain on a planar projection of the knot (Fig. 2B). The simplest and most abundant type is the trefoil (or 3_1) knot, but there is one protein featuring the Stevedore's (or 6_1) knot (with 6 crossings) (Börlinger et al., 2010). Recently, the 6_3 knot was found in a human protein (Perlinska et al., 2023). An interesting example is that of protein UCH-L1, the most abundant in the human brain (Sjölin et al., 2022), which features the gordian (or 5_2) knot. Knots can be further classified as deep, when the minimal segment of the polypeptide chain that contains the knot (knotted core) is located at least 10 residues away from the termini, or shallow if this distance is smaller. Protein YibK, featuring a deep trefoil knot, is one of the most extensively studied knotted proteins (Fig. 2C–E).

Despite being statistically rare (Lua and Grosberg, 2006) these tangled molecules have attracted considerable attention, and the last decade witnessed a battery of experimental and computational studies dedicated to disclosing their folding and knotting mechanisms, and determine their biological function (Faisca, 2015; Jackson et al., 2017; Jackson, 2020).

The protein folding transition

In the 1930s, Anson and Mirsky observed that protein denaturation is a reversible process (Anson and Mirsky, 1934). Likewise, the refolding process observed after complete protein denaturation offers a operational setup to study protein folding *in vitro*. Protein denaturation can be chemically induced (e.g., by means of a denaturing agent such as urea or guanidinium chloride) or thermally induced by increasing temperature. Calorimetric experiments framed on differential scanning calorimetry, where the heat capacity is measured as a function of temperature, show that thermal denaturation resembles a melting process, with the heat capacity peaking at the so-called melting temperature T_m (or denaturation temperature) (Fig. 3A). At T_m both the protein's energy and entropy increase sharply with temperature as intramolecular interactions break and the system gains conformational freedom.

The transition from folding to unfolding is described by a sigmoidal (or S-shaped) curve depicting the fraction of folded protein over temperature or denaturant concentration (Fig. 3B). An S-shaped curve indicates an abrupt change is some measurable property at the transition midpoint, T_m . If the width of the transition region is narrow, it means that many amino acids are involved in the process. In fact, S-shaped curves are a hallmark of cooperative physical processes, i.e., processes in which the elements composing the system act dependently of each other.

In the case of protein folding, the abrupt change upon denaturation led Anson and Mirsky to introduce the two-state approximation for the folding-unfolding transition to indicate the absence of intermediate states populated in thermal equilibrium at T_m . Under this model, the folding process is a two-state cooperative transition. When the transition is two-state, the microscopic

Heat capacity curve showing a peak of heat capacity at T_m (B). The area under the curve is a measure of ΔH_{cal} . Microscopic distribution of protein conformations over a measurable property expected for a two-state transition (C, top panel) with σ_H being the standard deviation of H . The latter decreases as the equilibrium population shifts from a bimodal to a unimodal distribution (C, mid and bottom panels). Free energy profile (projection of the free energy over a reaction coordinate, e.g., H) expected for a two-state transition (D). Dependence of the folding rate constant on the concentration of denaturant showing typical linear chevron behavior. The chevron roll-overs also displayed in the graph are an indication of the presence of intermediate states populating the folding transition (E).

distribution of protein conformations at T_m is bimodal, indicating that only the native and denatured states coexist in equilibrium at that temperature (Fig. 3C, top panel). A projection of the free energy into an appropriate property (e.g., the protein's energy or enthalpy) shows a free energy barrier separating the two thermodynamic states (Fig. 3D).

In experiments *in vitro*, the so-called calorimetric criterium is often used to determine if protein folding is an “all-or-none” two-state transition (Zhou et al., 1999). Accordingly, a transition is two-state when the ratio between the measured calorimetric enthalpy change, and the effective two-state van't Hoff enthalpy change ($\Delta H_{vH} = 2\sigma_H$) is unity (Fig. 3C) (Chan et al., 2004). However, it turns out that it is not a sufficient condition (Zhou et al., 1999). Indeed, for the transition to classify as two-state, the so-called chevron-plots (showing the dependence of folding and unfolding rate on the concentration of denaturant) must show strongly sloping linear refolding arms (Chan et al., 2004) (Fig. 3E). Most small (~with up to 120 amino acids), single-domain proteins fold thermodynamically via a two-state transition and with single-exponential kinetics (Jackson, 1998). Because of their simplicity, they became the preferred model systems to study protein folding.

The thermodynamic hypothesis and the paradox of Levinthal

In the 1950s, Cristian Anfinsen performed a series of experiments with protein ribonuclease A (RNase) that ended up launching the field of protein folding (Anfinsen, 1973). RNase is an enzyme with a chain length of 124 amino acids. Its native structure is stabilized by four disulfide bonds. Anfinsen used a reducing agent (called beta-mercaptoethanol) to break the disulfide bonds, and urea to disrupt the secondary structural elements and he noticed that the protein became biologically inactive, i.e., it denatured. Subsequently, by simultaneously removing the two chemical agents, he observed that the protein regained activity, i.e., it refolded back into its biologically active native conformation. Anfinsen concluded that since refolding occurred spontaneously, the native conformation in its normal physiological milieu (solvent, pH, ionic strength, presence of other components such as metal ions or prosthetic groups, temperature and other) is the one in which the Gibbs free energy of the whole system is the lowest; and since refolding did not require the addition of other chemicals, the native conformation must be determined by the totality of interatomic interactions and hence by the amino acid sequence in a given environment. This conclusion, known as Anfinsen's dogma, or thermodynamic hypothesis, granted Anfinsen the 1972 Nobel Prize in Chemistry.

In the late 1960s, Cyrus Levinthal noted that the number of atomistic-level conformations of a protein is massive (Levinthal, 1968, 1969). A lower bound estimate for this number can be obtained as follows. Assume that an amino acid can only be in two distinct conformations. In this case, a small protein with ~ 100 amino acids would have access to 2^{100} (or 10^{30}) conformations. Assume additionally that a conformational change occurs so fast that it only takes 1 ps for an amino acid to move between two conformations. If protein folding is really a two-state process without intermediate states, the time needed to fold (i.e., to find the native conformation that corresponds to the global minimum of the free energy) can be estimated from the time needed to randomly explore all possible conformations. This time is astronomically large. In fact, even for the simplest case considered above, it would take 2^{100} ps or 10^{10} years to find the native structure. But generally, small proteins fold fast in the timescale of milliseconds to seconds (Jackson, 1998). This quantitative argument is known as Levinthal's Paradox. According to Levinthal, the goal of achieving a global minimum of the free energy is not compatible with doing it fast, and in his own words 'if the final folded state turned out to be the one of lowest conformational energy, it would be a consequence of biological evolution, not of physical chemistry' (Levinthal, 1969).

Levinthal's paradox represents a landmark in the history of protein science because it prompted and stimulated research on the kinetics and mechanisms of protein folding: What is the physical mechanism according to which proteins acquire their native structure in a biological timescale? Levinthal himself proposed that folding should be under kinetic rather than under thermodynamic control. This means that the folding process should proceed through the population of specific intermediate states that form a folding pathway. In his view, the native structure should be - not the global free energy minimum - but a kinetically accessible minimum that is sufficiently deep to trap the protein's conformation in a thermodynamically stable state. In 1992, kinetic trapping was observed in the folding reaction of a designed protein, but the corresponding state was not biologically active (Baker and Agard, 1994). In 1996, a model for a kinetically controlled folding pathway as envisioned by Levinthal was suggested for protein Serpin Plasminogen Activator Inhibitor 1 (PAI-1), which forms a metastable active structure that converts slowly to the more stable but low-activity 'latent' conformation (Wang et al., 1996). While the possibility that folding may be under kinetic control for some model systems should not be ruled out, the fact that robust, stable proteins can be designed by focusing on the stability of the target structure, indicates that thermodynamics must generally outcast kinetics in protein folding (Baker, 2019). In fact, the analysis of early lattice models suggested a correlation between thermodynamic stability and kinetic accessibility of the native structure (Shakhnovich and Gutin, 1993) and, for some small proteins, thermodynamic stability, as measured by the free energy of folding (ΔG_U), correlates strongly with folding rate (Plaxco et al., 2000).

In recent years, folding intermediates have attracted considerable attention because of their potential to trigger the aggregation process. This has been shown in experiments *in vitro* (Le Marchand et al., 2018; Neudecker et al., 2012) and predicted by molecular simulations (Kroboth et al., 2012; Estácio et al., 2014; Loureiro et al., 2017). We note, however, that such species are not necessarily intermediate states in the thermodynamic sense. Most often they are indeed transiently populated and difficult to detect experimentally (Chiti and Dobson, 2009).

The energy landscape theory and folding funnels

Computer power increased dramatically throughout the 1990s, which allowed researchers to use computer simulations to study protein folding. In particular, coarse grained models like lattice models (Fig. 4A) and off-lattice C-alpha models (Fig. 4B) combined with Monte Carlo sampling were, and still are (Especial and Faísca, 2021), very popular among the molecular biophysics community. These models contributed to establish basic principles of protein folding (Kmieciak et al., 2016).

A landmark computational study explored the behavior of random heteropolymer (RHP) sequences featuring the 20 naturally occurring amino acids in the context of a lattice model (S'ali et al., 1994). It was found that 15% of the tested random sequences were able to find the native state (the maximally compact structure with the lowest energy) rapidly and reproducibly fold to it. What distinguished these proteinlike sequences from the non-folding ones was an energy gap between the native state and other unrelated conformations. Since natural protein sequences overcome the paradox of Levinthal, these results suggested that folding RHP are proteinlike sequences. Therefore, a necessary condition to fold fast is that the native state is a pronounced global minimum on the potential energy surface. Additionally, analytical calculations on lattice representations of hydrophobic (H)-polar (P) sequences predicted sharp cooperative transitions from unfolded conformations with very few HH interactions, to a native structure where the number of HH interactions are maximized (Dill et al., 1995). These results, and others alike, also indicated that folding does not proceed through a random search for the native structure because the number of accessible conformations decreases exponentially as the protein becomes progressively more compact through the establishment of native interactions. This behavior was theoretically described through the concept of folding funnel (Fig. 5), a major outcome of the so-called energy landscape theory developed by Wolynes and co-workers (Onuchic et al., 1997).

The energy landscape theory is a theoretical framework that conciliates Anfinsen's thermodynamic hypothesis with fast folding kinetics. It combined concepts from polymer physics with the theory of spin glasses and used insights from computer simulations of simple lattice models. The interested reader will find illuminating reviews on this subject in the works of Ken Dill and collaborators (Dill and Chan, 1997; Dill, 1999). Here, we briefly expose its main concepts and ideas.

The energy landscape is a multidimensional representation of the folding process where the vertical axis represents the internal free energy of a single conformation, while the multiple lateral axes represent the conformational coordinates (e.g., the dihedral bond angles, ϕ_1 - ϕ_1 , ϕ_2 - ϕ_2 , ...). The internal free energy of one conformation accounts for everything (i.e., hydrogen bonds, salt bridges, torsion angle energies, hydrophobic and solvation free energies, etc.) except for the conformational entropy. It is called free

Fig. 4 Protein models with different granularity used in simulations of protein folding. In both the lattice model (A) and the C-alpha model (B) each amino acid is reduced to a bead of uniform size (C). The lattice model restricts the beads to occupy the vertices of a regular lattice, with the lattice spacing mimicking the peptide bond. In the C-alpha model the coordinates of the C-alpha atoms are taken from the PDB native structure and the distance between them is set to a fixed value. In the full atomistic model, all atoms are explicitly represented (D). In (A) and (B) protein energetics is mimicked with sequence-specific or structured based potentials, and conformational space is explored with Monte Carlo methods, Langevin Molecular Dynamics, or Discrete Molecular Dynamics. When the solvent is explicitly represented (E) the conformational space is explored with classical Molecular Dynamics, and energetics is based on a force field (GROMOS, CHARMM, AMBER etc.) that is empirically parametrized.

Fig. 5 The folding funnel. Diagrammatic representation of a perfectly funneled shaped energy landscape representing a fast two-state folding transition (A). Energy landscape illustrating the paradox of Levinthal (B). In this case only the denatured and native ensemble can be populated, and the search for the native structure is unbiased. The folding chain randomly explores all denatured conformations until it finds the only one that provides access to the native state.

energy (and not merely energy) because of the solvation terms, which involve entropy due to water ordering. A point in the free energy landscape represents a protein conformation, and geometrically closed conformations lay close to each other. For a certain value of the vertical axis (i.e., of the internal free energy) there is an ensemble of conformations corresponding to some conformational entropy. On the top of the funnel, the unfolded ensemble is the largest one, with the highest conformational entropy. The width of the funnel progressively shrinks down as folding progresses reflecting the fact that the number of accessible

conformations progressively decreases as the chain approaches the native ensemble (i.e., the native conformation and nearby ones) at the bottom, with the lowest internal free energy (Fig. 5A). In the landscape perspective, folding is viewed as a succession of random conformational transitions starting from an arbitrary unfolded conformation. In its search for the native state the polypeptide chain will lower its internal free energy by shielding hydrophobic residues in the core, and by increasing its content in hydrogen bonds, number of salt-bridges, disulfide bonds etc. while it becomes progressively more compact (note that the paradox of Levinthal results from assuming an unbiased conformational search (Fig. 5B)). The funneled shape of the free energy landscape reflects the concomitant decrease in the chain's internal free energy and conformational entropy that occurs during folding. A chain navigating the folding funnel will rapidly attain the native state starting from an arbitrarily unfolded conformation by taking many possible routes (instead of populating a sequence of well-defined conformations as envisioned by Levinthal). Therefore, the folding process satisfies Anfinsen's thermodynamic hypothesis in a directed and rapid way. The folding funnel is, therefore, a conceptual insight that reconciles the thermodynamic hypothesis with the biological timescale of protein folding.

A rather provocative view, which challenges the traditional interpretation of protein folding, was recently proposed based on the so-called *excluding* interactions. The latter are steric clashes and unsatisfied hydrogen bond donors and acceptors which, despite being unspecific, can induce considerable chain organization. Conformations with disfavored interactions of this type will be largely excluded from equilibrium populations. Thus, under physical-chemical conditions that favor folding, excluding interactions substantially separate the accessible population. In doing so, they solve the problem of entropy loss (which is conventionally compensated by the formation of specific and stabilizing intramolecular interactions as outlined above) and also reduce the timescale of protein folding (Rose, 2021).

Folding mechanisms

The landscape perspective offers an ensemble view of protein folding that is, nevertheless, too generic to discriminate between the folding mechanism of different proteins. But what is the exact meaning of folding mechanism? In a recent review article (Nassar et al., 2021) Dill and co-workers provide a illuminating definition: a mechanism is a descriptor "of folding at a level that is sufficiently general and coarse-grained to apply to all proteins, and yet sufficiently granular to account for the differences across proteins." The idea that a mechanism is a sequence of physical events that bring a disordered unfolded chain into its ordered native structure is implicit in this statement.

Levinthal was one of the first researchers to propose a folding mechanism. The latter was based on the formation of nucleation sites, or local interactions that establish rapidly between residues which are close to each other along the chain (e.g., hydrogen bonds interactions that stabilize the secondary structural elements). The resulting secondary structural elements would then coalesce to form the tertiary structure. This is, in fact, the core idea behind the framework model (Wetlaufer, 1973), which envisions folding as a hierarchical process where the formation of secondary structure elements precedes the formation of the native structure. A different mechanism is the diffusion-collision model (Karplus and Weaver, 1979). In this case, the core part of protein folding are the diffusive encounters (or collisions) between metastable regions of the polypeptide chain that progressively leads to more stable intermediate states. In the 1970s, the so-called molten globule, an intermediate state that preserves the mean overall native structure but exhibits a looser packing and higher mobility at loops and termini, was proposed to be a common species in the folding process (Ptitsyn, 1995).

In the so-called hydrophobic collapse model (Dill, 1985), the initial event in protein folding is the collapse of the unfolded chain resulting from the hydrophobic effect. The formation of secondary structure occurs in this collapsed state and the packing of the sidechains eventually leads to the native structure.

However, perhaps one of the most popular folding mechanisms is the nucleation-condensation mechanism (reviewed in Faísca, 2009). As previously stated, small, single-domain proteins fold with a two-state thermodynamic transition, and their folding rate fits a single-exponential kinetic model. For these small proteins, folding is limited by the formation of a folding nucleus in the so-called transition state ensemble (i.e., the ensemble of conformations laying at the top of the free energy barrier). In the classical nucleation mechanism of first-order phase transitions the critical nucleus is a portion of the new phase, whereas in the folding transition the folding nucleus is a *specific set* of (local and non-local) intrachain interactions (Abkevich et al., 1994). The formation of the folding nucleus is rate-limiting. Thus, once it forms, the native structure is promptly achieved. Perhaps not surprisingly, Monte Carlo simulations of lattice models (in which intrachain contacts are straightforwardly and unequivocally determined), offered the first theoretical predictions for a nucleation mechanism. Experimentally, it is not possible to obtain a structurally resolved picture of the folding transition state using standardly used biophysical techniques due to its transient nature and being sparsely populated. Thus, a protein engineering technique termed ϕ -value analysis was developed to provide an indirect structural characterization from thermodynamic considerations (Itzhaki et al., 1995). The ϕ -value is defined as being the ratio between the change in the activation energy of folding ($\Delta\Delta G_{TS-D}$) and the change in the free energy of folding ($\Delta\Delta G_{N-D}$) upon performing a single-point mutation. For two-state proteins, a ϕ -value near unity means that the TS is perturbed upon mutation as much as the native state is perturbed. This is interpreted as if the mutated residue is in a native (or near native) conformation in the TS. Alternatively, a ϕ -value of zero means that the corresponding residue is as unstructured in the TS as it is in the denatured (D) state. The interpretation of fractional ϕ -values or non-classical ($\phi < 0$) or ($\phi > 1$) is not straightforward and may indicate partial contact formation or folding path heterogeneity (Best and Hummer, 2016).

By determining the ϕ -value of all the 64 protein residues in the single-domain protein chymotrypsin-inhibitor 2 (CI2), it was found that the folding nucleus comprises a set of predominantly local interactions stabilized by a few non-local ones, in line with the predictions from lattice simulations (Itzhaki et al., 1995). The lack of secondary and tertiary structure in the transition state was taken as evidence that they form concomitantly triggered by the folding nucleus. The nucleation-condensation mechanism appears to be common among many small, single-domain proteins, but it is unlikely that there is a unifying mechanism for protein folding. It has been proposed that an increased propensity to form stable elements of secondary structure, makes folding more hierarchical, eventually following a framework mechanism where the transition state is assembled from pre-formed secondary structural elements (Daggett and Fersht, 2003).

More recently, the use of a technique termed hydrogen-exchange pulse-labeling mass-spectrometry (HX MS) (Englander et al., 2016), which can detect and characterize local structure, even when it is only transiently present, has provided evidence that some proteins (including small ones such as Anfinsen's RNase) fold in a stepwise manner by populating distinct intermediates separated by kinetic barriers; these proteins fold through a folding pathway similar to that envisioned by Levinthal (Hu et al., 2013). The novel insight is that these intermediate states are formed by assembling small pieces (with about 20 residues) of secondary structure (helices, turns and beta-strands) termed *foldons*. Because of their small size, foldons resolve the timescale search problem. However, they are not individually stable being transiently populated, and need to accrete to gain stability and persist for a longer time. Interactions between foldons provide the free energy bias for the ordered addition of foldons in a stepwise pathway that sequentially builds the native protein. In this mechanism, known as the foldon funnel model, the free energy barrier is a consequence of the substantial entropy loss that results from ordered secondary structural elements, with the energetic gain due to native contacts not being enough to balance it (Rollins and Dill, 2014).

The folding mechanisms outlined above have been proposed by exploiting the folding of small proteins through simulations and *in vitro* experiments. However, research on larger, multidomain proteins is considerably less developed (Gershenson et al., 2020). Recent work suggests that even though these proteins can be broken down in smaller units by domain dissection (i.e., the identification of structural domains from the amino acid sequence by means of informatic methods), the folding of these component domains may not be independent. Consequently, the mechanisms guiding individual small, single-domain proteins may not be applicable to the universe of larger proteins (Hingorani and Gierasch, 2014). Moreover, there is evidence that the folding of large proteins *in vivo* may be context dependent, which means that *in vitro* and *in silico* studies may offer an incomplete, or even unrealistic, view of these processes as they happen in the living cell (Sorokina and Mushegian, 2018).

Folding kinetics

The question of understanding the mechanism(s) of protein folding is complemented by the question of understanding folding kinetics, i.e., the temporal laws and timescales that govern this self-assembly process.

As stated previously, many small, single-domain proteins fold rapidly (in the microsecond to millisecond time scale) via a two-state folding process where the only states populated in equilibrium are the native and the denatured states (Jackson, 1998). For these proteins, a plot of the natural logarithm of the rate constants for unfolding ($\ln k_U$), and refolding ($\ln k_F$), versus denaturant concentration, $[D]$, is frequently linear (linear chevron plots) (Fig. 3E). The corresponding kinetics is termed single-exponential because folding speed is limited by the height of only one free energy barrier corresponding to the transition state (Fig. 3D).

The speed at which a protein folds is quite sensitive to temperature. Early studies on Monte Carlo simulations of lattice models predicted that there is an optimal folding temperature, i.e., a temperature at which folding is fastest (Faisca and Ball, 2002a). This temperature is typically lower than the melting temperature, i.e., in conditions that favor the population of the native state. However, away from this optimum, both at higher and lower temperatures the process gets increasingly slower. In the first case, the protein tends to behave like an RHP rapidly fluctuating between unfolded states. In the second case, there is a high probability for the chain to get trapped into metastable states and folding entails overcoming the corresponding kinetic barriers. This kind of temperature-rate dependence was also observed in experiments *in vitro* (Oliveberg et al., 1995) and, more recently, in living cells (Guo et al., 2012).

From a physics point of view it is more relevant to understand how the structural features of the protein determine its folding rate. One, the chain length, is simply the number of amino acids, N , in the primary structure. A seminal study, combining concepts from statistical mechanics of random heteropolymers, and results from simple lattice models, formulated the relation $k_f \sim \exp(N^{1/2})$ between the folding rate, k_f , and the chain length (France, 1995). A later study that considered experimentally determined folding times for 69 proteins and peptides with size ranging from 16 to 396 residues found a correlation of 0.74 between the logarithm of folding time and $N^{1/2}$, and a maximum value of ~ 0.78 as the exponent approaches 0 (Naganathan and Muñoz, 2005).

A stronger correlation (of 0.91) was found between the logarithmic folding rates of a set of 24 small ($56 \leq N \leq 154$), single-domain proteins that fold with single-exponential kinetics and a parameter of native structure named relative contact order, CO (Plaxco et al., 2000). The latter is a measure of the average length of the backbone loops connecting contacting pairs of residues in the native structure,

$$CO = \frac{1}{LN} \sum_{i,j} \Delta_{ij} |i - j|,$$

where L is the total number of contacts, and $\Delta_{ij}=1$ if residues i and j are in contact and is 0 otherwise, $|i-j|$ is the backbone separation between residues i and j . A protein whose native structure is predominantly dominated by interactions between amino acids that are

far away in sequence has a high-CO, whereas interactions that are predominantly local should render a low-CO. The relative contact order fails to predict the folding rates of short peptides and large multistate folding proteins (Ivankov et al., 2003), for which the chain length seems to be the major determinant of folding time (Galzitskaya et al., 2003). Thus, it is important to understand why the CO predicts the folding rates of small, single-domain proteins.

The first computational study that investigated the CO-rate correlation in the context of lattice models used a pairwise additive potential and found a moderate correlation (0.70), but only for chains with number of amino acids $N \geq 54$ and high-contact order ($CO > 0.17$) (Faisca and Ball, 2002b). However, the folding rates underlined by this potential are far from exhibiting the six-order-magnitude difference observed in real small, single-domain proteins. A subsequent study, also framed on lattice simulations, suggested that the CO-rate dependency may require multi-body interactions (Kaya and Chan, 2003). Indeed, a coupling mechanism between local and non-local native interactions was able to render the folding transition more cooperative while simultaneously leading to highly dispersed folding rates, a necessary condition to observe a strong statistical correlation with the CO. Another lattice simulation study explored the CO-rate correlation in a set of model systems in which the effect of the CO in folding kinetics was isolated from other properties (e.g., native state stability) potentially affecting kinetics (Faisca et al., 2012). The considered model systems were designed to share the same native structure, but displayed different backbone connectivities and, therefore, different CO values. The results from this study suggest that the CO-rate correlation is a consequence of the fact that, in high-CO native structures, the contact order of the transition state ensemble closely mirrors that of the native state. This happens because in these high-CO structures the native topology is present in the transition state through the formation of a network of tertiary interactions that are distinctively long-ranged. Despite these and other alternative views (Makarov and Plaxco, 2003), no consensus was yet reached regarding the microscopic mechanism underlying the CO-rate correlation.

Folding and knotting

If understanding the folding process of topologically regular proteins is already challenging, doing it for deeply knotted proteins (which represent extreme cases of topological complexity) is even more difficult. However, the solution of the folding puzzle is not complete without solving the folding mechanism of knotted proteins.

Since it is not yet possible to obtain a structurally resolved picture of the knotting mechanism in laboratory experiments, molecular simulations have been playing a major role in providing theoretical predictions. According to the current picture, the knotting step occurs with highest probability in structurally consolidated (i.e., near native) conformations toward the final stage of the folding process. Two major knotting mechanisms have been observed in simulations: in one mechanism, the chain terminus that lays closer to the knotted core (i.e., the minimal segment of the chain that contains the knot), directly threads a loop formed by the remainder of the chain (Wallin et al., 2007; Faisca et al., 2010). In the alternative mechanism, the chain terminus arranges itself into a hairpin conformation that threads the loop, transiently forming a slipknot (Noel et al., 2013; Sułkowska et al., 2009) (Fig. 6).

Because the formation of the loop must precede the threading event, the folding process of knotted proteins is highly ordered. This means that if native or nonnative interactions are formed untimely, they must break and re-establish later. The folding process of knotted proteins is thus prone to backtracking, and knotted proteins tend to exhibit slower folding kinetics (Soler et al., 2014; King et al., 2010).

It has been shown by experiments *in vitro* using a cell-free translation system, i.e., a minimal kit containing the necessary machinery for transcription (the production of messenger RNA, mRNA, from a DNA template) and translation (where the ribosome, reads the mRNA and synthesizes a polypeptide chain with the correct amino-acid sequence), that deeply knotted proteins can spontaneously self-tie (Mallam and Jackson, 2012; Lim and Jackson, 2015). However, this type of experiments also showed that the folding rate of deeply knotted proteins can be increased by at least one order of magnitude through the addition of chaperonins. The latter are a class of cylindrical shaped complexes featuring an interior cavity that works as an infinite dilution chamber. Together with chaperones they assist folding *in vivo* (Saibil, 2013) (Fig. 7). According to the classical mechanism

Fig. 6 Knotting mechanism. The knotting step involves the formation of the knotting loop by one portion of the polypeptide chain. The latter is directly threaded from one of the termini in the direct threading mechanism, or threaded by a hairpin forming a slipknotted conformation.

(also termed Anfinsen's passive model) the chaperonin accelerates folding by preventing off-pathway aggregation (Hayer-Hartl et al., 2016). However, this does not seem to be the case of knotted proteins, and it has been proposed that the chaperonin facilitates unfolding of kinetically and topologically trapped intermediates, or that it stabilizes interactions that promote knotting (Lim and Jackson, 2015). Computer simulations suggest that the steric confinement provided by the chaperonin decreases the entropic barrier to knotting (Soler et al., 2016), while intermolecular hydrophobic interactions established between the protein and the chaperonin surface decrease the melting temperature, which facilitates the unfolding of trapped intermediates (Especial et al., 2019). Additionally, it has been proposed, based on molecular simulations, that ribosomes can assist the folding of knotted proteins by actively forcing the positioning of the knotting loop in a way that allows for a penetration by the threading segment (Chwastyk and Cieplak, 2015; Dabrowski-Tumanski et al., 2018a).

Conclusion

The principles of protein folding have been established from results obtained for small, single-domain proteins (~100 amino acids long) that fold fast, and in the absence of detectable intermediate states. These proteins, however, do not represent the majority of proteins in a cell's proteome, with the average protein featuring ~450 amino acids. Moreover, these results derive from studies framed on computer simulations of single chains, and from experiments *in vitro* where folding occurs in ideal conditions, at high dilution, in the simulated environment of the test tube.

The cell offers a completely different environment, with the cellular cytoplasm being highly crowded, with macromolecular concentrations ranging between 200 and 400 mg/ml (Fig. 7A). It is inevitable to wonder whether these assumptions may be oversimplifying, in the sense that system size and cellular environment may change the analysis at a fundamental level (Fremberg-Kesner and Elcock, 2013; Ostrowska et al., 2019).

Large proteins, often comprising multiple domains and subdomains, are expected to have complex folding processes with multiple folding routes and populate stable intermediate states. Additionally, is more likely that their folding process is initiated during synthesis on the ribosome (Waudby et al., 2019) (Fig. 7B). Furthermore, recent experimental evidence supports the view that, for large proteins, folding may be context dependent, which means that it may be not exclusively governed by the primary sequence. Is it possible that different, still unidentified physical principles may be at play in the folding of large proteins?

In the cellular milieu protein molecules are exposed to excluded volume interactions and become highly vulnerable to establish intermolecular interactions with other molecular species. The combination of these effects may affect native state stability, which becomes context dependent, and not intrinsically determined by primary sequence. Is it possible that the crowded, diverse cellular environment may be more than a neutral background for folding? (Yu et al., 2016) As we have seen in the case of knotted proteins, cellular components (including the ribosome and the chaperonin) (Fig. 7C and D) do affect the folding process. It remains to be ascertained up to which extent the physical constraints they impose, and the intermolecular interactions they induce alter the folding process with consequences for the folding code and for the principles that govern protein folding.

Research in protein folding will be inevitably shaped, perhaps dominated, by these kinds of ever more complex questions. Hopefully, AI research will evolve into physics-informed AI, whereby physical models can be transformed into descriptors within a machine learning framework, offering a promising route to establish “fundamental laws” for protein folding (Chen et al., 2023).

Abstract

Many devastating diseases are linked to an imbalance in protein folding. Efficient and correct protein folding is crucial for protein functions, including catalysis, molecular recognition, molecular transport, and cellular signaling. Additionally, if protein folding is unsuccessful or the protein cannot remain in its folded state, the accumulation of misfolded species results in many pathological conditions, including neurodegenerative diseases, cancers, diabetes, and cardiovascular diseases. Not surprisingly, despite advances in our understanding of protein folding, it remains one of the fundamental questions in biology and biomedicine. Here, I discuss current experimental approaches for the characterization of protein folding using solution Nuclear Magnetic Resonance (NMR) spectroscopy.

Key points

- A non-expert introduction to the basic concepts of protein folding
- A non-expert review of the main strategies for the characterization of protein folding by NMR
- Discussion of the latest developments and limitations

Introduction

The understanding of protein folding (a process by which a polypeptide chain spontaneously folds to a specific 3D conformation called a native state) has provided critical insights into the fundamental principles of life and helped develop new therapeutics for protein-folding diseases. One of the central dogmas of the protein folding field, formulated by Christian Anfinsen in 1962 (Anfinsen et al., 1961; Anfinsen, 1972, 1973), states that the 3D structure of a protein is uniquely determined by its amino acid sequence and is stabilized by the non-covalent interactions between amino acids. As a result, in a physiological environment, the protein will spontaneously fold into its native conformation driven by the minimization of its free energy. However, given the complexity of a protein molecule, if a protein has to sample all possible conformations to find the free energy minimum, the time required for the protein to fold to its native conformation through a random search would be far longer than the age of the Universe. This paradox was first described by Cyrus Levinthal in 1969 (Levinthal, 1969), who questioned why proteins fold so quickly [the characteristic times for protein folding are μ s–seconds (Kubelka et al., 2004)] and efficiently despite the vast number of possible conformations that they can adopt. It now has been widely accepted that while driven by the minimization of the protein's free energy (as described by Anfinsen's 'thermodynamic dogma'), proteins fold through a series of intermediate states called the protein folding pathway (Dill and Chan, 1997). Different proteins have different levels of complexity of their protein folding pathways (Mecha et al., 2022; Nassar et al., 2021) that range (depending on protein size and sequence) from a simple, one-step folding directly into a native state without passing through intermediate structures to the complex, multistep process that requires the formation of multiple intermediates. These intermediates are essential stepping stones toward the native structure, directing and facilitating the folding process (Brockwell and Radford, 2007).

In general, the protein folding pathway can be described in terms of a funnel-shaped protein folding landscape (Fig. 1) that represents the relationship between the protein's conformational space (entropy) and its free energy (Dill, 1985; Dill and Chan, 1997; Leopold et al., 1992; Tsai et al., 1999; Roder and Wales, 2022; Karplus, 2011). The protein folding process can be considered as a search for the native state (representing the lowest free energy and entropy minima) from a disordered state(s) (representing the highest free energy and entropy). Together with global minima (native states), the protein folding landscape also includes local minima that represent multiple, on-pathway intermediates (ones that contain native-like contacts and support protein folding), as well as off-pathway (non-productive) intermediates and misfolded/aggregation-prone states. By competing with the native state(s) and on-pathway intermediates kinetically and/or thermodynamically, the off-pathway states often determine the rate

Fig. 1 *The complexity of protein folding:* The protein folding energy landscape consists of various folding intermediates that a protein can adopt before reaching its native (folded) state. As a nascent polypeptide chain emerges from the ribosome, it is exposed to the cellular environment that can significantly impact protein folding by modulation the stability of intermediates, promoting or hindering specific folding pathways, and influencing the kinetics of the folding process. Interactions with ribosomes and ribosome-associated chaperones can guide protein folding and prevent misfolding. The binding and release of molecular chaperones at different stages of folding ensure the fidelity of the folding process. Created with BioRender.com.

and efficiency of protein folding (Brockwell and Radford, 2007). Moreover, by decreasing the kinetic barriers of off-pathway reactions, the off-pathway states can favor protein aggregation, a (irreversible) process by which individual protein molecules come together to form large insoluble structures. These insoluble species are often thermodynamically more stable than native states (Mecha et al., 2022). The formation of such aggregates (e.g., amyloid fibrils) is thought to be a key factor in progression of many protein folding diseases, including Alzheimer's disease, Parkinson's disease and type II diabetes (Knowles et al., 2014; Chiti and Dobson, 2017; Hartl, 2017; Tittelmeier et al., 2020).

Many amylogenic proteins, including amyloid- β , tau, and α -synuclein, are fully or partially intrinsically disordered (Bowman et al., 2020; Pauwels et al., 2017). Unlike globular proteins that adopt one or few folded conformations, about 30–50% of eukaryotic proteins remain intrinsically disordered in solution or contain intrinsically disordered regions (IDRs) longer than 30 residues (Dunker et al., 2000; Bondos et al., 2021). How these proteins can perform specific biological functions without adopting a well-defined structure remains highly elusive. Interestingly, IDP conformational heterogeneity and flexibility are essential for IDP functions such cellular signaling and gene regulation as it enables multivalent interactions with several binding partners and IDP functional diversity (Uversky, 2021). The multifunctionality of many IDPs is based on their ability to fold into well-defined structures as a response to external triggers such as binding to small molecule ligands, communication with other proteins or post-translational modifications (Uversky, 2021; Wright and Dyson, 2009; Piersimoni et al., 2022). However, this conformational flexibility also has an important disadvantage as it increases the ability to misfold and aggregate.

Protein folding and misfolding are also influenced by mutations or/and environmental factors such as pH, temperature, pressure or salt concentrations. Understanding how environmental factors affect the folding process is a critical question to be addressed (Brasemann et al., 2013). Inside the living cell, the crowding environment, physiological and pathological stresses, and unspecific and specific interactions with other macromolecules and/or small molecules make protein folding even more complicating (Gershenson and Gierasch, 2011; Qin and Zhou, 2017; Hingorani and Gierasch, 2014; Brasemann et al., 2013). Unsurprisingly, most proteins require special folding machines called molecular chaperones that ensure efficient protein folding under normal and stress conditions (Hartl et al., 2011; Jayaraj et al., 2020; Wilson et al., 2023). Molecular chaperones are key players in protein quality control (PQC) that act at different stages of the protein folding process to ensure the formation of the native state(s) from a newly synthesized nascent chain. They also maintain the integrity of proteins by detecting misfolded proteins, refolding them or delivering them to the degradative enzymes (Torner et al., 2022; Tittelmeier et al., 2020). Not surprisingly, protein misfolding and aggregation are usually linked to a failure of the PQC machinery to maintain protein homeostasis inside the cells (Hartl, 2017; Hartl et al., 2011).

There are more than 300 types of molecular chaperones in human cells (Jayaraj et al., 2020) that work synergistically and sequentially to ensure that proteins inside the cell are correctly folded and functional in health and under specific environmental and metabolic conditions (reviewed elsewhere (Hartl et al., 2011, Jayaraj et al., 2020)). For example, Hsp70 chaperones bind to newly synthesized nascent chains, preventing non-functional interactions and the formation of off-pathway intermediates (Mayer and Gierasch, 2019). Following Hsp70 acting, Hsp90 (Moran Luengo et al., 2019) and Hsp60 (Hayer-Hartl et al., 2016; Gestaut

et al., 2019) chaperones recognize and interact with later folding intermediates, stabilizing them and providing a favorable environment for folding. Other molecular chaperones (e.g., Hsp104 and its prokaryotic homolog ClpB) play an important role in the degradation of misfolded proteins and aggregates, ensuring that these toxic species do not interfere with cellular processes (Lin et al., 2022; Fauvet et al., 2021). The molecular chaperones are dynamic molecular machines that undergo ATP-dependent (e.g., Hsp70, Hsp90, Hsp100) or ATP-independent (e.g., small heat shock proteins or sHSPs, trigger factor) conformational changes to control the affinity and specificity of binding to their client (unfolded) proteins (Balchin et al., 2016). Understanding the mechanisms by which molecular chaperones recognize their client protein substrate and synergistically assist their folding is another key research area in the field.

Nuclear Magnetic resonance (NMR) spectroscopy has been one of the central tools to characterize protein folding both *in vitro* and *in vivo* (Zhuravleva and Korzhnev, 2017; Cawood et al., 2021; Alderson and Kay, 2021; Dyson and Wright, 2005). Solution NMR is particularly powerful in the elucidation of molecular details about complex protein folding pathways, including the characterization of short-living intermediate states that populated during the protein folding process and transient aggregation-prone folded conformations (Alderson and Kay, 2021). Recent developments in fast acquisition methods (including non-uniform sampling and processing algorithms) allows real-time characterization of folding processes with the ms resolution (Kremer et al., 2011; Charlier et al., 2018a; Pinter and Schwalbe, 2020). Furthermore, the development of new labeling scheme (deuteration, methyl NMR, ^{19}F -labeling) and NMR experiments dedicated for characterization of large proteins (Arthanari et al., 2019), enables characterization of complexes between molecular chaperones and their unfolded protein clients (Karamanos and Clore, 2022), nascent chain folding on ribosomes (Waudby et al., 2022) and even inside the living cells (Luchinat et al., 2022). NMR, together with other state-of-the-art biophysical techniques, allows some of the complexity of protein folding now beginning to be unraveled. This report provides an overview for non-experts that discusses how solution NMR can be used to address key questions in the protein folding field. I highlight some recent NMR achievements that enable the characterization of the challenging and fascinating process of protein folding.

Basic principles of NMR

For the first time (in 1946), nuclear magnetic resonances were reported by Bloch et al. (1946) and Purcell et al. (1946). Since then, NMR has become one of the most powerful techniques to investigate inorganic and organic molecules and complex biological systems such as multidomain proteins, protein complexes, enzymes, allostery, dynamic interactions between macromolecules and more. The physical principles of NMR are based on the quantum mechanics of nuclear spin angular momentum and have been reviewed in detail elsewhere (Cavanagh et al., 2006). This chapter provides a brief, simplistic overview of the basic NMR terminology.

Spin magnetic momentum: Bio-NMR is a spectroscopic technique that allows observation of NMR active nuclei in biological macromolecules. Atoms with spin $\frac{1}{2}$, such as ^1H , ^{13}C , ^{15}N , ^{19}F and ^{31}P , are usually used for bio-NMR due to their favorable relaxation properties. When a nucleus with a spin $\frac{1}{2}$ is inserted into an external magnetic field B_0 (an NMR spectrometer), its spin magnetic momentum begins to move on a cone around the magnetic field, keeping a constant angle between the spin magnetic momentum and the field. The frequency of these motions (precession), called Larmor frequency, is proportional to the magnetic field and equal to:

$$\omega_0 = \frac{\Delta E}{\hbar} = -\gamma B_0,$$

whether γ is a characteristic constant for a given nucleus, called a gyromagnetic ratio; $\hbar$ is a Planck's constant; and ΔE is the energy level splitting of the spin in a magnetic field B_0 (called Zeeman splitting).

Chemical shift: Although atoms and molecules vigorously move around in solution, it has little effect on the precession of a spin angular momentum for a specific nucleus as it only depends on the magnetic field. However, due to these fluctuations, the surrounding electrons and nuclei produce a small, rapidly fluctuating magnetic field that is slightly different from the external (static) magnetic field in amplitude and direction. As a result, the local magnetic field around a specific nucleus rapidly fluctuates, resulting in a shielding effect which depends on electron density and electronegativity of neighboring groups. Consequently, a spin resonates at a unique (different from other spins of the same type) frequency that depends on its local (chemical) environment. These small, environment-induced differences are referred to as a chemical shift that can be defined as:

$$\delta = \frac{\nu - \nu_{\text{ref}}}{\omega_0} \times 10^6,$$

whether ν is a resonance frequency of an atomic nucleus, ν_{ref} is a reference frequency from a standard molecule, and ω_0 is the Larmor frequency of the corresponding atom type. Chemical shifts are independent of the static (external) magnetic field and measured in parts per million (ppm). Chemical shifts can be also converted to Hz (usually referred to ω) by multiplying the chemical shift value in ppm (δ) by ω_0 . Because chemical shifts reflect the local (chemical) environment around a specific nucleus, they can be used to extract information about a molecule's local and global structure and dynamics. In turn, changes in chemical shifts allow monitoring of chemical reactions (e.g., phosphorylation, ATP hydrolysis, etc.), binding to a small molecule ligand or a macromolecule, as well

as structural and dynamic changes (e.g., due to local or global unfolding) upon external perturbations such as mutations, changes in temperature or pH, and ligand binding.

Relaxation: While in the absence of the magnetic field, all nuclear spin orientations are equally likely, when the external magnetic field is turned on, the bulk longitudinal (along the external field) magnetization is gradually built on with the relaxation time constant T_1 . T_1 relaxation occurs due to angular fluctuations of relaxation-active interactions resulting in transitions that return the spin state back to equilibrium. Similarly, the longitudinal magnetization will gradually return to zero if the field is switched off. In turn, after being created by a radio frequency pulse, the transverse magnetization (that is perpendicular to the external field) follows a single exponential decay with the time constant T_2 . This happens due to the loss of phase coherence in the xy plane over time. The T_2 relaxation limits the duration of the NMR acquisition as the detected signal decays to zero over time; in a frequency NMR spectrum, T_2 determines the broadness of the peak that has width is equal to $1/(\pi T_2)$. Many modern NMR techniques [e.g., amide- and methyl-TROSY (transverse relaxation optimized spectroscopy)] exploit favorable relaxation properties of specific transitions to improve the sensitivity and resolution of NMR spectra, enabling characterization of large biological molecules that have a small T_2 (fast relaxation) and, as a result, a low sensitivity if traditional techniques are used for their characterization. Because T_1 and T_2 depend on the size of a molecule, internal motions of a nucleus, and external parameters such as temperature and viscosity, their measurements have been widely used to characterize protein conformational dynamics.

Chemical exchange: Consider that the protein of interest can co-exist in two conformations: the ground (native) state A and a low-populated (folded intermediate) state B. The two states undergo conformational exchange $A \xrightleftharpoons[k_{BA}]{k_{AB}} B$ with the exchange constant: $k_{ex} = k_{AB} + k_{BA}$. To calculate the population of states A and B, we can use the Boltzmann distribution (Neudecker et al., 2009):

$$\frac{p_A}{p_B} = \frac{k_{AB}}{k_{BA}} = e^{-\frac{\Delta G_{A \rightarrow B}(T)}{RT}},$$

where $p_A = k_{BA}/k_{ex}$ and $p_B = k_{AB}/k_{ex}$ are the populations of states A and B, respectively; R is the gas constant; and T is the absolute temperature. If there is no exchange between these two states (or exchange is slow on the NMR timescale) and the populations of both states are sufficiently large to be observed by NMR, two peaks appear in an NMR spectrum with chemical shifts ω_A and ω_B . If the exchange between the A and B states is significantly faster than the difference between ω_A and ω_B (fast on the NMR timescale), the precession frequency of an observed spin will change between ω_A and ω_B , resulting in one peak in the NMR spectrum with a chemical shift equal to the population-weighted average of ω_A and ω_B . In the case of intermediate exchange (if the exchange rate is comparable with the difference between ω_A and ω_B), the exchange process significantly increases the transverse relaxation rate constant ($R_2 = 1/T_2$), resulting in broadening of peaks in the NMR spectrum. Different NMR techniques can study this contribution in the transverse relaxation to extract information about rate constants of different exchange processes as well populations and chemical shifts of exchangeable states (Clore, 2022; Anthis and Clore, 2015).

Magnetization transfer: All modern bio-NMR techniques measure the response of nuclear spins to a radio frequency (rf) pulse that irradiates the sample with a frequency close to the Larmor frequency of the specific nucleus to create desired nuclear magnetization. Most NMR experiments consist of more than one rf pulse divided by variable delays during which the selected magnetization is allowed to evolve and transfer between NMR active nuclei in specific ways. This approach allows magnetization transfer between different atoms, enabling multidimensional homonuclear and heteronuclear bio-NMR experiments. In general, the magnetization can be transferred from one nucleus to another through either covalent bond(s) connecting two nuclei or space. Magnetization transfer through bond, known as scalar or J-coupling, plays a key role in 2D and multidimensional NMR, coupling different atoms of the same type (e.g., COSY and TOCSY experiments) or different types (most 2D and multidimensional bio-NMR experiments). Magnetization can be also transferred from one nucleus to another without direct covalent bonding through cross-relaxation or spin diffusion mechanisms. When two nuclei are close together (within 6–10 Å), the magnetic field of one nucleus can affect the magnetic polarization of the other nucleus. This effect can be measured by NMR, providing information about the distance between two nuclei (NMR nuclear Overhauser effects).

Isotope labeling: Not all nuclei are NMR active, and not all NMR active nuclei have spin $\frac{1}{2}$. For example, ^{12}C has spin 0 (NMR inactive) as it has six protons and six neutrons; however, its stable isotope ^{13}C has seven neutrons and six protons with a net spin of $\frac{1}{2}$. Similarly, ^{14}N has spin 1 (NMR active but unsuitable for bio-NMR); however, its stable isotope ^{15}N has a spin $\frac{1}{2}$. Consequently, most of the modern bio-NMR approaches require ^{15}N and/or ^{13}C labeling (Fig. 2) because proton NMR has very limited applicability due to the complexity and overlapping issues of ^1H NMR protein spectra. Moreover, it is challenging (if even possible) to assign NMR peaks for any protein larger than 10 kDa using ^1H NMR only. Heteronuclear correlation experiments improve the resolution in protein NMR spectra, facilitating the resonance assignments and interpretation of NMR data. Uniform labeling of all ^{13}C and/or ^{15}N atoms is the most commonly used approach for small protein and isolated domains (up to 20–30 kDa). However, for larger systems (>30 kDa), deuteration is usually essential to obtain good quality NMR data. For larger proteins, ^1H -dependent relaxation mechanisms cause a significant broadening of NMR peaks and, as a result, a drastic decrease in peak intensities. Perdeuteration (uniform substitution of all or a significant part of ^1H atoms with ^2H), in turn, significantly suppresses these effects and enables the NMR characterization of 30–200 kDa protein systems, including multidomain proteins and protein-protein complexes. Furthermore, selective $^{13}\text{CH}_3$ labeling of methyl-containing side-chains in combination with a highly deuterated background enables NMR studies of protein complexes and oligomers up to 1 MDa (Tugarinov et al., 2006).

Fig. 2 *Isotopic Labeling Strategy for Protein NMR*: The protein of interest is expressed in a suitable host organism (usually *E. coli*) using a recombinant expression system; the protein needs to be produced in high yield to obtain sufficient material for NMR studies. The host organism is grown in an isotopically enriched medium. For example, ^{15}N -labeled proteins are produced by growing bacteria in a medium containing ^{15}N -labeled ammonium chloride; similarly, ^{13}C labeling is achieved by incorporating ^{13}C -labeled glucose. The isotopically labeled protein is then purified using standard techniques, such as affinity chromatography and size-exclusion chromatography, to remove other cellular components and impurities. The purified labeled protein is used for NMR experiments to provide information on protein conformation, structure, dynamics, and interactions. Created with BioRender.com.

NMR approaches to characterize protein folding

NMR for characterization of transiently populated intermediates: As discussed in Introduction, most proteins populate on- and off-pathway intermediates during their folding processes. These ‘alternative’ protein states are challenging to characterize due to their low populations, short life times, and conformational dynamics. However, while only transiently populated, these intermediates often play critical roles and define the efficiency of folding and, thus, protein function. Moreover, some of these intermediates have a toxic effect on a living cell or favor the formation of insoluble oligomers (Cawood et al., 2021). Consequently, understanding how and why these intermediates are formed during the folding process is an extremely challenging but fundamental task in the protein folding field. NMR is one of the most powerful techniques to tackle this challenge and has been successfully used to obtain detailed structural, kinetic and thermodynamic details about folding intermediates for several protein systems (Korzhnev and Kay, 2008; Cawood et al., 2021).

One way to characterize folding intermediate is to perform experiments under static conditions, often using destabilized protein variants, small concentrations of denaturants or high pressure or temperature to perturb the folding landscape and enable the equilibrium population of partially folded intermediates to achieve the detectable level. While, in some cases (if several sets of signals corresponding to the folded, unfolded, and intermediate states are observed in the NMR spectrum), it is possible to stabilize and characterize folding intermediates or misfolded species directly (Eliezer et al., 1998; Ropson and Frieden, 1992; Ferrolino et al., 2013; Bhatt et al., 2020; Low et al., 2008; Dreydoppel et al., 2022; Kakeshpour et al., 2021; Panova et al., 2019), such characterization of transiently (0.5–10%)-populated (as called invisible or dark) states are usually not possible due to sensitivity issues. Several NMR approaches have been developed to exploit μs -ms exchange between the major and excited (minor) states to transfer information (e.g., chemical shifts) about an ‘invisible’ minor state to the major state and then detect it (Fig. 3). There are three main

Fig. 3 *Characterization minor, invisible protein states using advanced NMR techniques*: Folding intermediates are transient, partially folded conformations that populated during the folding process (left); they often have regions of native-like secondary structure, but their tertiary structure is not fully formed. They are typically short-lived and difficult to observe directly. Off-pathway intermediates, in turn, are conformations that deviate from the productive folding pathway, leading to non-native or misfolded states. They are often associated with the formation of higher-order protein structures such as non-functional oligomers and protein aggregates (right). Transient oligomers form through transient interactions between partially folded or misfolded intermediates. They can lead to non-native oligomeric structures, such as amorphous aggregates and amyloid fibrils. Characterization of transient oligomers can provide information about the factors and mechanisms governing protein aggregation. The advanced NMR techniques (such as CPMG, CEST, DEST, and PRE) can detect and characterize these minor protein states that are otherwise invisible to direct observation methods. Created with BioRender.com.

strategies to achieve this [reviewed in detail in (Clore, 2022, Anthis and Clore, 2015)]: (i) The relaxation dispersion (CPMG and R1 ρ) experiments (partially) suppress the exchange contribution into the T₂ relaxation. The suppression level can be attenuated in the experiments, and the level of attenuation can be then fitted to extract exchange parameters, including exchange rates, populations of each states and their chemical shifts. (ii) Chemical exchange saturation transfer (CEST) is based on the saturation transfer between two exchangeable states. If the minor and major states have significantly different chemical shifts, the minor state can be selectively saturated (temporarily show no net magnetization) using rf irradiation; this saturation is transferred to the major state due to the exchange process, resulting in a signal attenuation for the major state. This attenuation can be used then to calculate the parameters of exchange. Dark state Exchange Saturation Transfer (DEST) uses the same principles but without the requirement to have different chemical shifts between the visible and invisible states. This can be achieved in case of exchange between a smaller (visible) state and a very large (invisible) oligomeric or aggregation state that has a very broad signal and, thus, can be saturated far away from the resonances of the visible state. (iii) Paramagnetic Relaxation Enhancement (PRE) measurements require a paramagnetic probe(s) to be introduced to the protein of interest (usually attached to a cysteine residue). Atoms located close (within ca. 24 Å) to the paramagnetic probe have enhanced T₂ relaxation. To characterize the minor (invisible) state by PRE, the distance between the paramagnetic probe and the observable site must be significantly shorter in the minor state than in the major state so that the enhanced relaxation in the minor state (but not in the major state) is extremely fast. As a result, even a small population (<1%) of the minor state that interconverts with the major state, would affect the observable T₂ relaxation of the major state and can be, thus, detected.

These techniques have been successfully used to study folding mechanisms of several single-domain proteins, including detection and characterization of folding intermediates (Tollinger et al., 2001; Korzhnev et al., 2006, 2004, 2010, 2012; Neudecker et al., 2012; Tugarinov et al., 2015; Vallurupalli et al., 2019; Meinholt et al., 2022; Meinholt and Wright, 2011; Dyson and Wright, 2017; Tiwari et al., 2021). In addition, these techniques have been used to probe aggregation-prone conformations, misfolding and self-assembly processes that lead to the formation of large, non-functional aggregates (Alderson and Kay, 2021; Lim et al., 2013; Mukherjee et al., 2011; Karamanos et al., 2014, 2019; Kotler et al., 2019; Sekhar et al., 2015b; Culik et al., 2018; Wu and Baum, 2010; Fawzi et al., 2011). The information about folding/unfolding kinetics and thermodynamics can be mapped into folding pathways of the protein of interest, and, in some cases, NMR also provides structural details about transiently populated intermediates [reviewed in (Neudecker et al., 2009, Korzhnev and Kay, 2008, Zhuravleva and Korzhnev, 2017, Cawood et al., 2021)].

Hydrogen exchanges to probe folding intermediates and aggregates: Hydrogen exchange (HX) was one of the first tools to characterize protein folding and detect early folding intermediates (Hvidt and Nielsen, 1966; Schmid and Baldwin, 1979). Its combination with 2D amide NMR (Wagner and Wuthrich, 1982) further revolutionized the field, providing residue-resolved HX data. HX-NMR provides a residue-resolved protection map of NH groups that can be extrapolated into local flexibility and solvent accessibility, providing information about structural and dynamic features of different protein conformations (Anthis and Clore, 2015) or can be even used to predict a *de novo* tertiary structure (Marzolf et al., 2021; Nguyen et al., 2022).

In HX experiments (Fig. 4), the H- to D-exchange reaction of individual amide groups is monitored by placing the protein of interest into a D₂O buffer, allowing amide protons to exchange to deuterons (Bai, 2006). The rate of HX for individual NH atoms depends on both protein conformation and intrinsic amide hydrogen exchange rates and, thus, provide information about the solvent accessibility of individual NH groups and hydrogen bond stability. The exposure of an unfolded protein to D₂O results in very rapid HX. Because the formation of protein structure almost always involves H-bonding (that makes HX significantly slower), in a folded protein, the protons that are deeply buried (inaccessible for the solvent) have an intrinsic exchange rate (observed for unprotected amides) that is 10⁶–10⁹ times faster than the HX rate observed experimentally (Kuwajima et al., 2022). In turn, protons located in the flexible regions of a folded protein or partially unfolded state(s) are significantly less protected. Because HX experiments are performed under equilibrium conditions in which folded and unfolded (or partially folded states) are interconverting, the difference between intrinsic and observable HX rates for folded (stable) proteins depends on the rate of the event(s) that make NH groups are more accessible for exchange (exposed to the solvent and lack stable hydrogen-bonding). As a result, the level of protection (the ratio of the intrinsic rate to the observed rate) for individual NH groups in a protein provides information about the structural, thermodynamic and dynamic properties of the protein conformational ensemble.

While mass-spectrometry is also very powerful tool to monitor HX in proteins (James et al., 2022), the main advantage of NMR is the atomic resolution of HX data. Because deuterons are not observed in a 2D amide NMR spectrum (that contains peaks that correspond to individual amide groups in the protein), amide signals will decay after the protein is placed in D₂O because of the hydrogens exchange (Fig. 4). Deuterium incorporation for individual backbone amides can be extracted from a corresponding peak intensity. To obtain more detailed insights into the folding process, these experiments are often coupled with pressure changes or performed at different denaturant concentrations to perturb the folding landscape. While this approach has been now applied to characterize several protein systems [reviews in (Dyson and Wright, 2005) (Kuwajima et al., 2022)], it is only applicable for the characterization of exchange processes that are significantly slower than the time required to record an NMR spectrum. Recent advantages in NMR data acquisition [reviewed in (Felli and Brutscher, 2009, Quinn et al., 2018)] have shortened this time from 10–15 min to seconds. However, this time resolution is still not sufficiently fast for characterization of fast (μ s–ms) folding steps. Alternative approaches to probe HX that occur on a sub-second timescale (Hwang et al., 1998; Brand et al., 2007; Chevelkov et al., 2010; Fitzkee et al., 2011; Grzesiek and Bax, 1993), involve the transfer of the ¹H magnetization from water molecules to the protein through hydrogen exchange [reviewed in (Anthis and Clore, 2015)].

Fig. 4 Basic principles of hydrogen-deuterium (HX) exchange and NMR-based analysis: The rate of HX exchange depends on solvent accessibility, hydrogen bonding, and local structural dynamics. As a result, the rates of deuterium uptake vary significantly for folded, partially folded, and unfolded proteins (left). Unfolded proteins exhibit the fastest HX rates as they lack a well-defined secondary structure, leading to increased solvent exposure for the majority of backbone amide hydrogens. In the native folded state, proteins have well-defined secondary and tertiary structure, with many backbone amide hydrogens involved in hydrogen bonding, reducing accessibility to the solvent; these protected amide hydrogens exhibit slow HX rates. In turn, dynamic and disordered regions (e.g., loops) have faster HX rates. In partially folded states, such as folding intermediates, proteins possess protected regions with a native-like structure, while other (unprotected) regions may lack a well-defined structure. Protection factors calculated from the HX exchange rates provide residue-specific information about the stability of local protein structure and can reveal the presence of intermediate states or alternative conformations. NMR can be employed (right) to extract HX information with residual resolution: When exposed to D_2O , amide hydrogen atoms on a protein are gradually replaced by deuterium atoms. 2D NMR experiments, such as HSQC (Heteronuclear Single Quantum Coherence), monitor the changes in peak intensities as a function of HX time. Residue-specific HX protection factors, derived from NMR data, provide insights into protein conformation and dynamic, folding pathways and interactions. Created with BioRender.com.

Pulse-labeling is another HX approach that overcomes the time-resolution limitations of traditional 2D amide experiments (Dobson et al., 1994; Kuwajima et al., 2022). For pulse-labeling techniques, HX only occurs for a brief amount of time and then is quenched by transferring the protein to conditions that preserve its protonation state. This could be achieved by either promoting fast folding to a native (slow exchange) state (Bai, 2006) or placing the protein in an aprotic (containing no protons) solvent such as dimethyl sulfoxide (DMSO) (Zhang et al., 1995; Nishimura et al., 2005). 2D or 3D NMR experiments can be then recorded to extract the amount of incorporated 2H for individual amide groups. Importantly, the DMSO-quenched HX approach also overcomes one of the most critical limitations of NMR. While the majority of amide NMR techniques are only suitable for the characterization of relatively small (up to 30–40 kDa) protein systems, limited by the sensitivity and resolution of 2D amide NMR, the DMSO-quenched HX approach does not have this size limitation, enabling high-resolution HX data for large and challenging protein systems (Kuwajima et al., 2022). Moreover, because DMSO is very efficient in the solubilization of protein aggregates, including amyloid fibrils, the DMSO-quenched HX method has also been successfully used to obtain structural insights into the formation of insoluble aggregates and fibrils (Alexandrescu, 2001; Ippel et al., 2002; Hoshino et al., 2002; Vilar et al., 2012; Lee and Goto, 2012).

Real-time folding by NMR: An alternative approach to sample the protein folding landscape is to monitor the folding-unfolding transition under non-equilibrium conditions in real time (Fig. 5). This can be achieved by the dilution of solutions of chemical denaturants, salts, acids/bases, or by the temperature or pressure jump. The folding (or unfolding) process can then be monitored experimentally in real time. In this case, the time needed to perform these measurements should be significantly shorter than the observed process (Bartlett and Radford, 2009). Techniques such as fluorescence or circular dichroism combined with stopped-flow methods have been widely used for these measurements, providing insights into global folding/unfolding with high enough time resolution (Eaton et al., 2000; Roder et al., 2006). In principle, folded and (partially) misfolded states can be monitored by real-time NMR (Smith et al., 2015b) during a refolding process. Particularly, a set of consecutive NMR spectra need to be recorded to monitor changes in peak positions, broadening and/or intensities to obtain information about folded and (partially) unfolded states and

Fig. 5 Protein folding timescales and NMR approaches for characterizing different folding steps: Methods (such as CPMG, CEST and PRE) that probe μ s-ms dynamics allow the characterization of rapidly exchanging folding intermediates and aggregation-prone species. Amide exchange experiments are employed to investigate the solvent accessibility and hydrogen bonding network, revealing information about protein stability and relatively long-lived folding intermediates. Real-time NMR methods are applied to monitor protein folding events on intermediate time-scale, providing insights into the formation of secondary and tertiary structures during the folding process. Created with BioRender.com.

characterize kinetics and thermodynamics of the folding-unfolding transition (Zeeb and Balbach, 2004). Using a similar approach, the formation of insoluble (invisible for NMR) oligomers from smaller (visible) protein states can also be characterized by monitoring the decay of NMR signal intensities for the visible state over time (Mishra et al., 2009).

While real-time NMR enables the atomic level of details, it is an intrinsically slow method; the long acquisition time has been the main limitation of this approach. However, recent advantages in NMR techniques (Felli and Brutscher, 2009; Quinn et al., 2018) have pushed boundaries and created new opportunities for the characterization of faster folding and misfolding processes with the second-time resolution as well as allowing structural characterization of relatively short-lived (few hours) intermediates (Rennella et al., 2012; Karamanos et al., 2016; Rao Kakita et al., 2018; Kumar and Balbach, 2015). These techniques use sparse data collection strategies and/or a shorter delay between experimental repetitions that is needed for magnetization recovery (Mobli et al., 2012; Hyberts et al., 2014; Smith et al., 2015b; Kumar and Balbach, 2015) that enables recording 2D and 3D spectra one-two order of magnitude faster than conventional NMR techniques (e.g., few seconds *vs* few minutes for a 2D spectrum). In some cases, if reversible folding is possible, fast acquisition techniques can be combined with a multiple folding-unfolding cycle during a single 2D or 3D experiment, when the NMR data acquisition is synchronized with a protein folding/unfolding reaction induced by pressure (Kremer et al., 2011; Charlier et al., 2018a) or temperature (Pinter and Schwalbe, 2020). These approaches further increase the time resolution to milliseconds, opening new opportunities to gain detailed information about the kinetics and thermodynamics of fast folding transitions and obtain structural features of on- and off-pathway intermediates populated at the early stages of folding (Charlier et al., 2018a,b; Dubois et al., 2020) or misfolding (Barnes et al., 2019).

NMR for the characterization of intrinsically disordered proteins: Together with small-angle X-ray scattering, electron paramagnetic resonance, mass spectrometry, and Förster resonance energy transfer, NMR enables the characterization of highly dynamic unfolded states and intrinsically disordered protein (IDP) systems, providing atomic insights into their conformational dynamics and interactions (Uversky, 2020; Dyson and Wright, 2021). Different NMR approaches for IDP characterization have been recently reviewed in Dyson and Wright (2019), Milles et al. (2018), Naudi-Fabra et al. (2021), Camacho-Zarco et al. (2022), Karamanos et al. (2022), Schneider et al. (2019). These approaches exploit the fact that fully unstructured proteins have drastically different NMR parameters compared to folded proteins, including the poor dispersion of chemical shifts, near zero residual dipolar coupling values (that report on an average of bond orientations with respect to the magnetic field), internal flexibility on the ns time-scale that affects their T_1 and T_2 relaxation rates, only local residual contacts that results in short-range NOEs and PREs. Any deviations of the experimental NMR parameters from those predicted for a fully unstructured state can be then used to calculate local propensities for the formation of transient secondary structure and long-range contacts (Fig. 6) (Dyson and Wright, 2005).

For several IDP systems that can adopt more ordered structures upon binding to their partners (Shammas et al., 2016) or posttranslational modifications (Bah and Forman-Kay, 2016), NMR has been successfully used to probe and characterize the induced folding process [reviewed in (Dyson and Wright, 2021) and (Mollica et al., 2016)]. On the other side, many IDPs remain disorder upon complex formation and their complexes cannot be described by a single conformational state [as called ‘fuzzy’ complexes (Tompa and Fuxreiter, 2008)]. Instead of a well-defined binding site, such IDPs contain several short interacting motifs; while each of these motifs has only weak binding affinity (enabling transient and reversible interactions), the presence of multiple motifs on the same protein molecule ensures high-affinity binding. Bio-NMR has played a crucial role in the characterization of such interactions [reviewed in (Ahmed and Forman-Kay, 2022)], including a recent study of a ‘fuzzy’ complex between two fully disordered IDPs (Borgia et al., 2018).

While NMR is a potent technique for IDP characterization, the correct quantitative interpretation of experimental data for such systems is a highly challenging task due to the heterogeneity and complexity of their conformational ensembles. Indeed, the IDP ensemble consists of many structurally heterogeneous and dynamic conformations rather than a small set of well-defined structures. While in most cases, these conformations are interconverting on the fast NMR timescale (faster than hundreds of microseconds), NMR reports on a population-weighted average over the ensemble of interconverting conformations (Kosol et al., 2013). Consequently, interpreting such complex experimental data requires generating a representative conformational ensemble.

Fig. 6 Conformational ensemble characterization of intrinsically disordered protein using NMR techniques: Long-range NOE (Nuclear Overhauser Effects) and PRE (Paramagnetic Relaxation Enhancement) measurements can be used to identify through-space interactions within the conformational ensemble; RDC (Residual Dipolar Coupling) experiments, capturing weakly aligned protein molecules in an anisotropic medium, provide information on long-range order and secondary structure propensities; T1 and T2 measurements allow the assessment of local and global flexibility in the protein molecules; Chemical Shift Index (CSI) analysis uses chemical shift deviations from random coil values to predict secondary structure elements; Chemical Shift Perturbation (CSPs) analysis detects changes in chemical shifts upon mutations and/or environmental changes and reveals long-range interactions and structural and conformational changes in IDPs. Created with BioRender.com.

Assuming that all IDP conformations interconverting on the fast-experimental timescale (beyond the fast regime, an NMR observable no longer represents a population-weighted average), the conformational ensemble can be then defined as a set of relevant conformations and their respective populations that accurately describe the experimental data, including all (often transient) long-range and local interactions in the protein chain. There are two main approaches to derive ensemble models that correctly describe experimental data, discussed in details in (Karamanos et al., 2022; Camacho-Zarco et al., 2022; Gama Lima Costa and Fushman, 2022; Bonomi et al., 2017). In the first approach (reweighting methods), an initial *in silico* set of protein structures (conformations) are generated. Initially, experimental data are predicted for all conformations from this set, assuming that they have equal probabilities of contributing to experimental observables. The real experimental data are used to refine the ensemble and find an appropriate weight (population) for each conformation. The main advantage of reweighting methods is that new experimental data can be added at any moment to refine the ensemble, minimizing computational cost, but the success of these methods largely depends on whether the initial set of structures realistically represents the real conformational ensemble. The second approach exploits restrained molecular dynamics (MD) simulations to include experimental data in the force field. Incorporating experimental data as restraints for MD simulations allows more enhanced sampling of the protein conformational space that is otherwise unavailable due to limited computations resources.

Because the number of degrees of freedom for IDPs are drastically larger than the number of independent experimental observables, often several conformational ensembles can fit the experimental data equally well. Consequently, to be able to capture all critical features of the heterogeneous IDP ensemble, the characterization of IDP usually requires an integrated structural approach that combines data from NMR and complementary biophysical techniques such as single-molecule fluorescence energy transfer (smFRET), electron magnetic resonance (EPR), small angle X-ray scattering (SAXS), fluorescence correlation spectroscopy (FCS), chemical cross-linking, electrospray ionization mass spectrometry, and others, (Karamanos et al., 2022; Camacho-Zarco et al., 2022).

Protein folding in the presence of molecular chaperones: During the folding process, proteins expose hydrophobic motifs that are essential for the formation of the folding core but can also favors off-pathway interactions and, thus, misfolding (Hartl et al., 2011). Molecular chaperones recognize these exposed hydrophobic motifs and/or these off-pathway interactions in a protein chain. Different molecular chaperones interact with a wide range of client proteins at different stages of their folding pathway, giving them different roles in assisting and maintaining protein folding. It has been widely accepted that molecular chaperones affect the conformation of their client proteins either by altering the folding landscape (e.g., by favoring on-pathway contacts and/or disfavoring non-productive contacts in the protein chain) (Jayaraj et al., 2020; Tittelmeier et al., 2020) or/and stabilizing a native state under conditions in which the native state is energetically unfavorable (Goloubinoff et al., 2018). However, only very recently we have started to understand how molecular chaperones perform this complex task (Sucec et al., 2021; Macosek et al., 2021). Because different conformations of molecular chaperones and their client proteins have distinct NMR fingerprints (chemical shifts, relaxation times, etc.), NMR has provided a unique opportunity to address these intriguing questions (Burmann and Hiller, 2015; Karamanos and Clore, 2022).

Recent developments in NMR techniques enable the detailed characterization of large, multicomponent protein systems, transient interactions and protein-protein complexes, and disordered protein conformations (Burmann and Hiller, 2015). As a result, the detailed characterization of chaperone interactions with their full-length protein clients for several cellular chaperones has been obtained in the last decade [reviewed in detail in (Karamanos and Clore, 2022) and (Hiller, 2021)]. For example, NMR studies of Hsp70 interactions with its full-length substrates revealed that the substrate-binding cleft of Hsp70 promiscuously recognizes multiple binding sites in the same protein sequence (Clerico et al., 2021; Rosenzweig et al., 2017), directly selecting the unfolded (extended) conformation of their client proteins by binding to the sites exposed during the early steps of the folding process (Landry et al., 1992; Sekhar et al., 2018; Lee et al., 2015). These Hsp70-client interactions reshape its clients' folding pathway by destabilizing off-pathway long-range contacts (Sekhar et al., 2016, 2015a). In turn, NMR characterizations of the bacterial Hsp60 GroEL

demonstrated that this chaperone preferentially binds to late-folding intermediates (Landry et al., 1992; Goldberg et al., 1997) and stabilizes them relative to the fully folded and unfolded states (Libich et al., 2015); moreover, GroEL accelerates the transition rate between the fully folded states and folding intermediate (Libich et al., 2017).

NMR has also played a key role in the elucidation of transient ('fuzzy') interactions between molecular chaperones and their protein substrates. For example, the NMR characterization of Hsp90 demonstrated that this chaperone binds to their client proteins through an extended surface area reminiscent of 'fuzzy' complexes observed upon interactions between disordered proteins and their binding partners (Park et al., 2011a). It has been further demonstrated that these weak binding contacts that spread other Hsp90 structures enable more effective interactions with partially folded intermediates that expose hydrophobic and charged regions over a large surface area (Karagoz and Rudiger, 2015) (Moran Luengo et al., 2019). A similar multivalent ('fuzzy') binding mechanism has been also revealed by NMR for several ATP-independent chaperones, including bacterial trigger factor (Saio et al., 2014), Skp (Burmann et al., 2013; Salmon et al., 2016), SecB (Huang et al., 2016), Hsp40 (Jiang et al., 2019).

For the majority of molecular chaperones, their functions rely on ATP-dependent or ATP-independent conformational changes (e.g., changes in domain arrangements for Hsp70 and Hsp60 or oligomerization state for Hsp90 and small HSPs) that control binding to their client proteins and/or interactions with co-chaperones and other members of the protein quality control network. Without knowing the structural details of these conformational changes and interactions, our understanding of protein folding mechanisms would be incomplete. The large size of multidomain molecular chaperones was the main limitation for their NMR characterization until the early 2010s. For this reason, first NMR studies (for example, characterization of the isolated substrate-binding (Pellecchia et al., 2000) and nucleotide binding (Zhuravleva and Gierasch, 2011) domains of Hsp70 and the isolated domains of Hsp90 (Hagn et al., 2011)) were focused on characterization of isolated domains or truncated variants rather than on full-length chaperones. The methyl labeling approach that selectively labels $^{13}\text{CH}_3$ of methyl groups (Tugarinov et al., 2006) significantly enhances sensitivity due to the fast methyl group rotation and the presence of the three equivalent protons. As a result, this labeling scheme has made it possible to use NMR to characterize very large protein systems (Rosenzweig and Kay, 2014; Rossi et al., 2019) (up to 2 MDa) such as full-length chaperones and other protein quality control enzymes, enabling the comprehensive understanding of mechanisms for the regulation of their chaperone activity (Zhuravleva et al., 2012; Wieteska et al., 2017; Meng et al., 2018; Karagoz et al., 2011; Park et al., 2011b; Henot et al., 2022; Lopez et al., 2021; Faust et al., 2020; Rosenzweig and Kay, 2016; Rosenzweig et al., 2015).

Protein folding on ribosomes and *in vivo*: In *in vitro* studies, the refolding process usually starts with a relatively expanded state of a protein with the entire protein chain in solution. On contrast, *in vivo* protein folding starts co-translationally with the nascent chain still bound to the ribosome and molecular chaperones (Fig. 7). The rate of translation enables another level of control by providing a time delay for co-translational folding (Zhang and Ignatova, 2011) and reducing risk of formation of off-pathway contacts and misfolded species in the complex cellular environment (Rajasekaran and Kaiser, 2022; Braselmann et al., 2013). For most experimental techniques, the signal detection from the ribosome-bound nascent chain or in living cells is impossible due to the

Fig. 7 Molecular chaperones and ribosomes in protein folding: A newly synthesized protein emerges from the ribosome, and the complex folding process begins. It involves the formation of on-pathway folding intermediates that lead toward the native states (blue). In turn, the formation of off-pathway intermediates can potentially lead to midfolded and aggregated species (red). Molecular chaperones assist protein folding by preventing the formation of non-native contacts and stabilizing on-pathway intermediates. Created with BioRender.com.

large background signal. New improvements in NMR sensitivity and selective labeling have provided unique opportunities to observe NMR signals under these conditions and, thus, assess the complexity of protein folding on ribosomes (Waudby et al., 2022, 2021) and/or *in vivo* (Luchinat and Banci, 2018; Luchinat et al., 2022; Selenko and Wagner, 2007) at the atomic level.

The characterization of ribosome-bound nascent chain is still a challenging task for solution NMR due to its large size (ca. 2 MDa) and low sample concentrations (few μM). However, because nascent chains are overall dynamic, they can be observed against the 2 MDa (invisible by NMR) ribosome; uniform ^{15}N or $^{13}\text{CH}_3$ methyl isotope labeling enables selective observation of the nascent chain (arrested at a specific chain length) against other ribosomal proteins. As a result, co-translational folding has been extensively studied by NMR in the last 15 years (Hsu et al., 2007, 2009; Cabrita et al., 2009, 2016; Eichmann et al., 2010; Waudby et al., 2018; Deckert et al., 2021; Burridge et al., 2021; Cassaignau et al., 2021; Ahn et al., 2022; Wang et al., 2019). By providing information about the population of folded and unfolded conformations as well as site-specific structural and dynamic features of each state and their dynamic interactions with the ribosome surface, these studies clearly demonstrated that interactions with the ribosome alter thermodynamics and kinetics of the protein folding energy landscape (Waudby et al., 2022).

In 2001 the first in-cell NMR study from Dötsch and co-workers (Serber et al., 2001) demonstrated that solution NMR is suitable for characterize protein behavior with atomic resolution inside the living cells. Methodological developments of in-cell NMR in the last 20 years have allowed characterization of a number of proteins [reviewed in (Luchinat and Banci, 2018), (Luchinat et al., 2022) and (Tochio, 2012)], including in-cell high-resolution structure of small proteins (Sakakibara et al., 2009; Ikeya et al., 2016; Tanaka et al., 2019), characterization of IDPs (Smith et al., 2015a; Theillet et al., 2016; Burmann et al., 2020; Lopez, 2023), protein folding and stability in cell (Inomata et al., 2009, 2017; Banci et al., 2011, 2013; Danielsson et al., 2015; Smith et al., 2016), in-cell protein interactions with ribosomes (Breindel et al., 2018), and interactions between different molecular chaperones and its client proteins (Burmann et al., 2020).

To be able to observe protein in cells without strong interference from the background, two isotopically labeling approaches have been developed for in-cell NMR (Luchinat et al., 2022). The first approach requires the expression and labeling of the protein of interest directly in cells in which NMR experiments will be performed. However, enrichment with ^{15}N and/or ^{13}C , commonly used for these experiments, often results in a relatively large background signal due to unselective labeling of other cellular components. An alternative labeling approach can be used (Selenko and Wagner, 2007): The protein of interest is first labeled and purified elsewhere and then introduced into selected cells (e.g., bacteria, oocytes or mammalian cultured cells), resulting in background-free spectra. Another serious limitation of in-cell NMR is the presence of transient, unspecific interactions in crowded cells that can significantly compromise the quality of in-cell 2D and 3D NMR spectra (Wang et al., 2011; Mu et al., 2017; Burz et al., 2019). However, this limitation can be compensated by the choice of the cell type (Leeb et al., 2020; Thole et al., 2021), maintaining a consistence cellular background during the experiments, and using advanced NMR pulse-sequences that increase the efficiency of magnetization transfer (Burz et al., 2019). Alternatively, methyl NMR in combination with local deuteration, can be used to improve sensitivity (Dubey et al., 2021). Another approach to improve the quality of NMR spectra and increase the applicability of in-cell NMR to more complex systems is to exploit the high sensitivity of ^{19}F NMR spectroscopy [83% of ^1H (Arntson and Pomerantz, 2016)]. For ^{19}F NMR, fluorine-containing non-canonical amino acids are incorporated in the protein using fluorinated mimics of aromatic amino acids (Arntson and Pomerantz, 2016) or via an orthogonal translation system (Maranhao and Ellington, 2017), allowing background-free detection using 1D ^{19}F NMR spectra (Chan et al., 2022; Pham et al., 2023; Zhu et al., 2022; Luchinat et al., 2022).

Challenges and limitations

In the last 20 years, dramatic improvements in NMR methodology, hardware and software have opened new avenues for NMR: from automatic protein structure determination using deep learning algorithms (Klukowski et al., 2022) to real-time NMR analysis of living cells (Luchinat et al., 2022). As a result, solution NMR, combined with other structural and biophysical approaches, has become a key technique to address fundamental questions in structural biology, drug developments and biomedicine, including protein folding and misfolding. However, at this stage, several critical challenges have still to be addressed.

Characterization of the dynamic protein quality control network: During the folding process, a protein transiently and sequentially interacts with different molecular chaperones and other protein quality controls enzymes. In turn, the activity of molecular chaperones depends on highly dynamic conformational changes and transient interactions with co-chaperones and other chaperones. Moreover, this complex network of molecular chaperones is post-translationally controlled in real time (Nitika and Truman, 2017; Backe et al., 2020) to adjust the protein folding capacity in the constantly changing cellular environment. This complexity cannot be addressed with a single technique, including NMR.

Folding only of the small fraction of proteome has been characterized: NMR and other techniques have focused on the folding characterization of relatively small and well-behaved proteins (Braselmann et al., 2013). Larger proteins usually have a more complex folding pathway that contains several on- and off-pathway intermediates making experimental data analysis more complex and ambiguous. The combination of data obtained from solution NMR and other experimental techniques (electron microscopy, mass spectrometry, Förster resonance energy transfer, time-resolved X-Ray diffraction, and others) with deep learning algorithms similar to AlphaFold (Jumper and Hassabis, 2022), RoseTTAFold (Baek and Baker, 2022) and EVE (Frazer et al., 2021) is the obvious way to obtain a complete picture of how complex, multidomain proteins fold and/or how (partially) folded proteins interact with the protein quality control enzymes.

Sensitivity and size limitations: Despite the significant progress in NMR characterization of large proteins (Rosenzweig and Kay, 2014; Rossi et al., 2019) and the development of higher field strength (Quinn et al., 2018; Luchinat et al., 2021) that dramatically enhance sensitivity and resolution of NMR experiments, the atomistic characterization of large protein systems (such as protein complexes with ribosomes and/or molecular chaperones and co-chaperones) remains to be extremely challenging. While a single 1D and 2D NMR spectrum can be recorded using relatively low (μM) protein concentrations, more complex experiments that are usually used to assess protein structure and conformational dynamics require significantly higher (tens to hundreds μM) concentrations and longer (hours) experimental time. As a result, the success of an NMR characterization of complex systems still largely depends on protein behavior in an NMR tube, its stability and solubility.

Time- and cost-efficient NMR labeling and characterization: Protein characterization by NMR usually requires months of work for a well-trained NMR expert(s) that significantly limits the use of NMR by non-NMR research groups. Despite very promising progress (Li et al., 2021; Karunanithy and Hansen, 2021; Klukowski et al., 2022, 2023), the automation of different steps of NMR characterization (from the optimization of a labeling scheme and experimental conditions enabling sufficient spectra quality to automatic resonance peak assignments in NMR spectra and calculation of NMR parameters) is still under development.

Conclusion

Protein folding is a complex and dynamic process that depends on a protein amino acid sequence but is also controlled by the environment, including concentrations of salt and small-molecule metabolites, molecular crowding, unspecific binding to cellular components as well as specific interactions with ribosomes, molecular chaperones and other cellular proteins and macromolecules. Due to this multidimensional complexity, many aspects of protein folding still need to be better understood. Recent methodological advantages in NMR and isotopic labeling have been successfully addressing many of previous limitations, enabling the characterization of challenging systems such as large multidomain chaperone machines, transient complexes between chaperones and their protein substrates, highly dynamic intrinsically disordered and unfolded proteins and their interactions, short-lived folding intermediates and aggregation-prone species. Moreover, state-of-the-art achievements in computational methods have the potential to provide synergy links between sparse experimental data from NMR and other experimental techniques. In the long term, deep learning algorithms can be used to analyze large and complex datasets from different experimental techniques and identify patterns and relationships between the observed experimental data, protein folding landscape, its amino acid sequence and chaperone interaction pattern. Altogether, these developments are leading to unprecedented opportunities to understand the fundamental principles of the protein folding process in living cells with atomic details and opening new avenues for drug discovery and protein engineering.

Introduction

Unlike macroscopic scattering methods such as X-ray diffraction, electron microscopy, or neutron diffraction, nuclear magnetic resonance (NMR) delivers structural information indirectly by probing the local electronic and magnetic environment of a nuclear magnetic moment (spin) or by investigating spin–spin interactions, both in the presence of a static magnetic field. The choice of NMR methods to detect such interactions can be strongly related to the mobility of the molecule of interest. In fact, molecular motion, or more generally speaking, the overall molecular correlation time τ_c , can be used to classify the type of NMR techniques for studying structure at the atomic level. Solution-state NMR studies in proteins are usually applied to systems with an overall correlation time in the nanosecond regime, while solid-state NMR, the area of research discussed in this article, traditionally relates to long or infinite correlation times (Figure 1).

In general, an increase in molecular correlation time may result from large molecular size, interactions with an anisotropic environment or from a decrease in temperature. In the context of this article, such phenomena may be related to large proteins, proteins interacting with membranes, or protein aggregates that are indicated in a growing number of protein folding disease states. In all cases, the molecular correlation time becomes longer than the inverse of the magnetic resonance frequency and all possible molecular orientations in the magnetic field are sampled in the NMR frequency spectrum. Unlike in solution, the spectral resolution and the overall sensitivity of solid-state NMR are furthermore influenced by the size of the nuclear spin interactions. Recent progress in NMR instrumentation, in particular the combination of ultrahigh magnetic fields (i.e., above 14 T) with rapid sample rotation (discussed in more detail below) has considerably improved the use of solid-state NMR in biophysical applications.

So far, such conditions have not permitted a widespread application of high-resolution ^1H NMR spectroscopy, the most sensitive detection method in solution, but have greatly extended the possibilities for studying multiply or uniformly [^{13}C , ^{15}N]-isotope-labeled polypeptides with high sensitivity and adequate spectral resolution. In this article, an overview of the principal interactions that can be probed in NMR is provided, and a set of high-resolution solid-state NMR (HR-SSNMR) techniques that permit the detection of multiple structural parameters from a single protein sample or NMR data set, is introduced. In general, solid-state NMR spectra directly report on the conformational heterogeneity of the sample. Maximum spectral resolution is often obtained for proteins exhibiting a high degree of structural homogeneity. Hence, particular attention is placed on sample preparation and isotope labeling schemes. Finally, the possible range of applications of HR-SSNMR for the structural investigation of solid-phase (membrane) proteins is exemplified in three cases.

Interactions

The microscopic interactions that can be probed by NMR techniques are summarized in Figure 2 and encompass the chemical shielding, the quadrupolar coupling, the dipolar coupling, and the scalar coupling. The chemical shielding describes the interaction between a nucleus and the applied magnetic field, as mediated by the environment of the nucleus. It is observed as a shift in the resonant frequency, with isotropic and anisotropic contributions. In general, chemical shielding information can directly deliver information about the local electronic environment of a spin or the molecular coordination. In addition, for applications in polypeptides, the resulting resonance frequencies are not only diagnostic for each individual peptide residue but are also very sensitive to local backbone conformation.

Figure 1 Typical ranges of molecular correlation times accessible to solution-state and solid-phase NMR.

Figure 2 Summary of the four principal interactions probed by NMR. While chemical shielding and quadrupolar interactions involve only one-spin interactions, dipolar and scalar coupling refer to two-spin contacts.

The second interaction is the quadrupolar coupling, between the electric quadrupole moment of a nucleus and the electric field gradient at the nucleus. Only nuclei with a spin quantum number greater than $1/2$ possess an electric quadrupole moment, making this interaction unimportant when dealing with spin- $1/2$ nuclei such as ^1H , ^{13}C , and ^{15}N . On the other hand, naturally abundant ^{14}N and deuteration with ^2H spins (both spin- 1) may yield novel insights into the details of polypeptide structure and, in particular, dynamics. In addition to the interactions probing local chemical environments, two-spin interactions are invaluable tools for studying protein structure. For example, the dipolar coupling between pairs of nuclei, of either the same species (homonuclear) or different species (heteronuclear) directly reports on internuclear distances. This coupling is anisotropic in nature, having the same dependency upon spatial rotation as the anisotropic part of the chemical shielding. Finally, spin-spin interactions may be mediated by the through-bond coupling, also known as the scalar or J -coupling. This is an isotropic interaction between nuclei (homo- or heteronuclei) modulated by the bonding electrons. Both the dipolar and J -couplings can be exploited to transfer magnetization between nuclei, giving invaluable information about the proximity (dipolar) and bonding (J) of the nuclei.

In solutions, the rapid tumbling of molecules leads to an averaging out of the anisotropic interactions. In solids, these interactions remain and directly influence the detected NMR spectra. Because the dependence upon spatial rotation of both the chemical shift anisotropy (CSA) and the dipolar coupling is given by $3 \cos^2 \theta - 1$, where θ is the angle between the z principal axis of the interaction and the applied magnetic field, spinning a sample at an angle of 54.7° to the field axis results in a strong suppression of the anisotropic components of both interactions. The corresponding technique is known as magic-angle spinning (MAS). When MAS is combined with decoupling of the ^1H nuclei (whose dipolar couplings are larger and not generally removed by MAS) the line widths of many nuclei, including ^{13}C and ^{15}N , are narrowed toward values observed in solution-state NMR. By removing the dipolar and CSA interactions under ultrahigh magnetic fields (i.e., above 14 T), MAS makes the acquisition of high-resolution solid-state NMR spectra possible.

In addition, a variety of radio frequency (RF) NMR techniques have been developed to recover the structural information contained in the four interactions of Figure 2 under MAS conditions. Some of these NMR schemes rely solely on particular settings of the MAS rate and are called rotor-driven recoupling techniques. Other techniques, known as radio-frequency-driven polarization transfer techniques, employ a series of RF pulses to overcome the effects of MAS or chemical shift perturbations and allow the detection of specific structural parameters in high resolution.

Sample Preparation

In general, for HR-SSNMR based studies on proteins, [^{13}C , ^{15}N]-isotope labeling is mandatory. Labeling patterns ranging from the incorporation of specifically [^{13}C , ^{15}N]-labeled amino acids to uniform [^{13}C , ^{15}N] substitution are often most economically generated during bacterial growth in minimal media. In addition, chemical synthesis, such as fluorenylmethoxycarbonyl (Fmoc) chemistry, or cell-free approaches can be employed to produce isotope-labeled polypeptides. In both cases, structural studies using

solid-state NMR can be performed using a variety of macroscopic sample preparations. For globular proteins, NMR experiments can be conducted after lyophilization and subsequent rehydration, which often increases the structural homogeneity of the sample. For the same purpose, precipitants such as polymers (e.g., polyethylene glycol, PEG) or organic solvents can be added that can lead to nano- or microcrystalline material. In the context of membrane proteins, structural studies have been conducted using frozen, detergent-solubilized specimens or liposomes in which the protein of interest has been reconstituted. Finally, fibrillized proteins have been extensively studied using solid-state NMR.

The highest sensitivity is usually achieved if the sample of interest is studied under MAS conditions using randomly oriented samples. In addition, macroscopically oriented samples, for example, mechanically oriented biopolymers or membrane-reconstituted peptides, aligned on thin polymer films, can be studied under fast MAS conditions. Furthermore, macroscopically oriented systems can also be investigated after orientation onto glass plates in static experiments or under MAS conditions.

Structural Analysis Using Solid-State NMR

Spectral Assignment

Of particular importance in the context of studying multiply or uniformly labeled proteins are polarization transfer methods employing scalar or dipolar two-spin interactions. Because of the isotropic character of the scalar coupling, polarization transfer mediated by through-bond interactions between two nuclei generally proceeds in an oscillatory manner, irrespective of the macroscopic orientation in the magnetic field (Figure 3a). In contrast, polarization transfer transmitted by through-space interactions under MAS conditions is dependent upon the orientation θ , of the dipolar vector in the static magnetic field. Integration over all possible molecular conformations can lead to a polarization transfer behavior, as depicted in Figure 3b, where positive and negative signal buildup corresponds to zero-quantum or double-quantum transfer, respectively.

An essential first step in NMR studies of multiply labeled proteins is the spectral assignment, based on the known amino acid sequence. Chemical shifts can be used to distinguish between general types of nuclei (e.g., ^{13}C nuclei in carbonyl (CO) and alpha (C_α) positions) but, for a full assignment, correlation experiments are necessary. These experiments generate two-dimensional (2D) spectra in which pairs of nuclei in close proximity are correlated. Two types of experiments exist, designed to establish intra- and inter-residue correlations. Different ^{13}C spin topologies of the amino acids give characteristic intra-residue correlation patterns, allowing the ^{13}C resonances to be assigned to the different residue types. Experiments for acquiring these correlation spectra may use single-quantum or double-quantum signal in an indirect dimension to separate out different contributions to the simple one-dimensional spectrum.

Figure 3 Analytical transfer functions for a two-spin system (denoted by the spin operators I_{1z} and I_{2z}) for the case of (a) the J -coupling and (b) the dipolar coupling. In both cases, the spin pair was initially prepared with magnetization only on spin 1. The transfer of polarization is subsequently monitored as a function of the mixing time (given in ms).

To acquire inter-residue information, ^{13}C nuclei can be correlated with ^{15}N nuclei in the same residue and the adjacent residues. This requires selective transfer of polarization between ^{13}C and ^{15}N in order to generate the desired indirect dimension and to ensure good resolution in the direct dimension. A common method involves two experiments, carried out on uniformly ^{13}C and ^{15}N labeled samples. In the first, magnetization is transferred from the backbone ^{15}N nuclei to the adjacent carbonyl (CO) ^{13}C and then, in a subsequent step, on to the α ^{13}C nuclei. This links the ^{15}N in residue i to the ^{13}C nuclei in residue $i-1$ (Figure 4, upper row) and is, in general, referred to as an NCOCA correlation experiment. In the second experiment, magnetization is transferred from the peptide bond ^{15}N nuclei to the nearest neighbor $^{13}\text{C}_\alpha$ spin, linking the ^{15}N and ^{13}C nuclei within the same residue. A subsequent (^{13}C , ^{13}C) transfer step leads to C_β resonance of the same residue corresponding to an NCACB-type experiment (Figure 4, lower row). From these two experiments, all backbone ^{13}C and ^{15}N nuclei of the polypeptide can be investigated.

Secondary Structure

The secondary structure of a protein encompasses the arrangement of the backbone atoms, depicted in Figure 5a. As the bond lengths are invariant, the secondary structure is largely defined by the torsional angles $\text{CO}(i-1)-\text{N}(i)-\text{C}_\alpha(i)-\text{CO}(i)$ and $\text{N}(i)-\text{C}_\alpha(i)-\text{CO}(i)-\text{N}(i+1)$, known as the φ and ψ angles, respectively. These may be measured in a variety of ways. A strong correlation exists between the ^{13}C chemical shifts at the C_α and C_β positions and the values of φ and ψ . In particular, the two main backbone conformational types, the α -helix and the β -sheet, may be distinguished by comparing these ^{13}C chemical shifts to the average chemical shifts (so-called “random-coil” values) for each amino acid. An example of the strong correlation between, so-called, secondary chemical shifts $\Delta\delta$ and the torsion angle ψ is shown in Figure 5b for a U- $[^{13}\text{C}$, $^{15}\text{N}]$ -labeled sample of the SH3 domain from α spectrin.

Dihedral angle constraints may also be determined directly by experiments monitoring the relative orientation of the appropriate internuclear vectors. This encoding can be carried out by allowing the dipolar interactions to generate cross-peaks in a correlation spectrum characteristic of their relative orientation or by creating a multiple-quantum state that evolves under the influence of surrounding dipolar interactions. Distance measurements are also important for the determination of secondary structure. For example, the $H_\alpha(i)-H_N(i+1)$ distance is a sensitive measure of the ψ torsional angle and can be probed by indirect detection schemes in solid-state NMR. Specifically, ^{13}C and ^{15}N labeled samples can also be used to measure distances between residues, which are sensitive to the φ and/or ψ angles. In both cases, experiments are used which involve dipolar recoupling between the two nuclei of interest. The buildup of either magnetization transfer or double-quantum coherence depends upon the internuclear distance and may be analyzed by appropriate theoretical or numerical models to give a measure of the distance. Of particular importance for structural characterization of side chains are HCCH and HNCH torsional angles, both of which can be measured using the methods outlined above.

Tertiary Structure

In order to establish the overall fold of a protein, distances must be measured between separate parts of the peptide chain. For a long time, the determination of these long-range contacts represented a major challenge for solid-state NMR due to an effect known as dipolar truncation, where the strong, short-range dipolar interactions dominate weaker, long-range interactions. As a result, relay effects over several short-range interactions may determine the spin system dynamics. These problems are most serious for uniformly $[^{13}\text{C}$, $^{15}\text{N}]$ -labeled proteins. Three approaches have been recently suggested to circumvent these difficulties. One is to dilute the isotope labeling of the protein by, for example, block labeling. A second approach involves the use of selective recoupling methods that establish polarization transfer for particular two-spin systems only. Finally, useful information may be obtained from an analysis of (^1H , ^1H) contacts, which is common practice in solution-state NMR. Because of the limited spectral resolution in

Figure 4 Graphical representation of NCOCA (upper row) and NCACB (lower row) correlation experiments that lead to spectral assignments in HR-SSNMR.

Figure 5 (a) The arrangement of atoms in the backbone of a protein. (b) The correlation between protein backbone structure, i.e., ψ , and secondary chemical shifts $\Delta\delta$ correlating C_α and C_β ^{13}C resonances obtained for the SH3 domain from α spectrin. $\Delta\delta$ is defined by the difference of observed (obs) and random coil (rc) C_α and C_β chemical shifts: $\Delta\delta = (\delta_{C_\alpha}(\text{obs}) - \delta_{C_\alpha}(\text{rc})) - (\delta_{C_\beta}(\text{obs}) - \delta_{C_\beta}(\text{rc}))$.

solid-state ^1H NMR spectra, such interactions may be encoded indirectly in high-resolution ^{13}C and/or ^{15}N spectral dimensions. Correspondingly, the 2D NMR experiments have been denoted by CHHC and NHHC correlation methods, respectively.

Similar to the solution-state, NMR structure determination in the solid state subsequently involves the calculation of families of molecular conformations that are consistent with the experimentally derived distance or angle constraints. The number and precision of these parameters determine the accuracy of the resulting 3D structure.

Protein Orientations, Interactions, and Dynamics

In addition to revealing structural information about the protein in a near-biological environment, the orientation of the protein with respect to a macroscopic reference frame (for example, one defined by the membrane bilayer for membrane peptides and proteins) can be investigated. The application of such methods often involves the NMR study of macroscopically aligned polypeptides and has resulted in several high-resolution structures of membrane-embedded systems. Furthermore, interactions between different proteins, proteins–ligand interactions (e.g., involving drugs, hormones, etc.), or monomer–monomer interactions in oligomeric proteins (quaternary structure) can, in principle, be investigated by high-resolution solid-state NMR.

Applications

In the following, three examples for the range of structural problems in immobilized proteins that can be addressed by high-resolution solid-state NMR are given. In Figure 6, results of 2D CHHC correlation experiment conducted on a uniformly [^{13}C , ^{15}N]-labeled sample of the 2×10.4 kDa dimeric form of the regulatory protein Crh in microcrystalline form are shown. Each correlation reflects close proton–proton contacts encoded in ^{13}C resonance frequencies. Three sections are highlighted where short, inter-residue (^1H , ^1H) distances are observed. A combination of these results with NC correlation experiments discussed earlier leads to NMR assignments of the largest protein studied by HR-SSNMR thus far and provides the basis for investigating the Crh folding pathway from a monomeric, soluble protein to a domain-swapped dimer observed in the microcrystalline state. Domain-swapping is a process by which one protein molecule exchanges a domain with an identical partner, and has been discussed as a general means for creating protein complexes and as a mechanism for misfolding and aggregation.

Solid-state NMR not only can report on the complete structure of a membrane protein but can also probe dynamics in the protein of interest. Both aspects have recently been investigated in the context of a uniformly [^{13}C , ^{15}N]-labeled version of the LH2 light-harvesting complex, one of the largest membrane systems studied by solid-state NMR to date (~ 150 kDa). Here, the application of ultrahigh magnetic fields (up to 750 MHz) was crucial to establish high-resolution conditions in the solid state. Two-dimensional (^{15}N , ^{13}C) correlation experiments (such as shown in Figure 7) were conducted to assign backbone and side-chain resonances at different temperatures. At -10°C , a variety of spectral assignments within the transmembrane sections of the protein were possible. Additional correlations occur at lower temperatures consistent with the immobilization of flexible loop regions of the protein. A more detailed structural study in membrane proteins could include (^{13}C , ^{13}C) or indirect (^1H , ^1H)

Figure 6 2D CHHC correlation experiment conducted on a uniformly [^{13}C , ^{15}N]-labeled sample of the 2×10.4 kDa dimeric form of the regulatory protein Crh. Each correlation reflects close proton–proton contacts encoded in ^{13}C resonance frequencies. Three sections are highlighted where short, inter-residue (^1H , ^1H) distances are observed: A – involving Gly49 and Ser46, B – Pro18 – Leu10, and C – a variety of C_α – C_α contacts.

correlation experiments possibly in conjunction with advanced isotope-labeling approaches, to determine the complete 3D structure of a membrane protein in the solid state.

To date, no structural information of a high-affinity ligand bound to a G-protein-coupled receptor (GPCR) is available. The recombinant expression of GPCRs in large quantities is usually difficult and must involve carefully optimized biochemical procedures. Restrictions regarding the availability of functional receptors also affect the quantities of ligand that can be studied. Moreover, the chemical environment including lipids and receptor protein can hamper the unambiguous spectral identification of a bound ligand in a solid-state NMR experiment. It has been recently shown how 2D solid-state NMR experiments can be used to detect microgram quantities of bound neurotensin, a 13-residue neuropeptide that binds in high affinity to the NTS-1 (101 kDa) receptor. For the 6-residue, biologically active, C-terminal sequence of neurotensin, a homonuclear (2Q, 1Q) correlation spectrum is sufficient to assign all C_α and C_β resonances of the uniformly [^{13}C , ^{15}N]-labeled ligand. These chemical shift assignments can be used to construct the backbone model of the ligand complexing with the receptor. Using the only high-resolution structure of a GPCR, rhodopsin, as a template, this information could be used to establish a molecular model for the binding pocket of NT(8-13) (Figure 8).

Conclusion

In many research fields, NMR methods have made important contributions to the present understanding of molecular structure and function. In particular, NMR has become a standard method for the characterization of 3D structure and dynamics of proteins that undergo fast molecular reorientations in solution. Such macroscopic sample conditions are, however, difficult to establish for protein aggregates, which are associated with a growing number of protein folding diseases. Moreover, integral membrane proteins, which constitute about 30% of all proteins, are often difficult to solubilize or crystallize in functional form. In all these cases, NMR techniques particularly designed for the study of solid-phase systems (“solid-state NMR”) offer unique possibilities to elucidate structural or dynamic parameters at atomic resolution.

In this article, a summary of high-resolution solid-state NMR methods that permit the detection of multiple structural parameters from a single protein sample or NMR data set is given. Recent applications in (membrane) proteins underline the growing potential of HR-SSNMR to provide exclusive insight into the microscopic details of biological functioning. Advances

regarding sample preparation (for example, including modular labeling, *in vitro* expression, and intein technology) and improvements in NMR hardware instrumentation could open up additional areas of solid-state NMR research, such as the investigation of large protein–protein complexes or the complete 3D characterization of larger membrane proteins. Solid-state NMR studies of multiply labeled biomolecules will furthermore profit from improved procedures for calculating 3D structures, in particular, in the presence of ambiguous or a limited number of structural constraints. In general, protein motion does not hinder the application of solid-state NMR methods, providing a very efficient means of studying protein folding, flexibility, and function under biologically relevant conditions. Complementary to solution-state techniques and crystallographic methods, solid-state NMR can give detailed insight into protein structure and function.

Introduction

Proteins are the most diverse of biological macromolecules, both in the structures they adopt and the functions they perform. Proteins are essential in all biological processes, acting as catalysts in the form of enzymes, in structural roles such as collagen and keratin in skin and hair, in the transport of small molecules such as oxygen by the protein hemoglobin, in the immune response in the form of antibodies, and in the regulation of all cellular processes acting as receptors and mediators of cellular signaling pathways.

Proteins are linear-chain polymers of amino acids, of which there are twenty naturally occurring building blocks. The condensation of the monomeric amino acid units into a polymer produces what is known as the polypeptide chain. Each protein has a specific sequence of amino acids which is encoded by the DNA of the gene for that protein. Proteins vary in length, the shortest are ~40–50 amino acids or residues long, whilst the longest, such as the giant muscle protein titin, can be over 10000 residues in length. Many proteins, however, are much smaller than this, typically between 200 and 300 amino acid units. This article focuses on how, relatively small proteins, that is to say those that are 100 residues or less in length, fold.

Proteins are produced in cells on ribosomes, the cellular machines for the synthesis of proteins. When it is first made, the polypeptide chain is in a highly flexible and conformationally dynamic state. In this state, the protein is referred to as being “unfolded” or “denatured” and it is not active. The polypeptide chain has to collapse into a specific, compact, and tightly packed folded state, known as the native state, before it can perform its physiological function.

The protein-folding field emerged in the early 1960s with the seminal work of Christian Anfinsen who showed that all the information necessary to specify the final three-dimensional structure of a protein was encoded in its primary amino acid sequence. How, after synthesis, an unfolded polypeptide chain collapses into a specific, compact, and tightly packed folded state, is the protein-folding problem. Up until the late 1980s, most of the work in the field focused on proteins with disulfide bonds or *cis*-prolines, as in these systems stable intermediates were observed which could be characterized experimentally. In these cases, folding is limited not by folding *per se*, but by the formation or rearrangement of disulfide bonds or isomerization of the prolyl peptide bond. Whilst these processes are interesting in themselves, they provide little information on the conformational changes occurring in the protein that result in the formation of a stable native state. In the late 1980s, protein engineering techniques were first employed along with rapid-reaction kinetics to characterize the folding pathways of a number of small proteins. In contrast to earlier studies, in these studies, the rate-limiting steps probed corresponded to folding and not some slower rearrangement or isomerization event. This approach to studying protein folding has now been widely adopted by the experimental protein-folding community and has provided data critical for the development of new protein-folding mechanisms and in benchmarking numerous computational studies. Here, the main features of the protein engineering methods are outlined and the work in this field over the last ten years, which has led to the determination of the energy landscapes for folding at atomic resolution for several small proteins, is summarized.

Protein Engineering

With the advent of recombinant DNA technology in the 1970s and 1980s came the ability to rationally and specifically engineer proteins. Over the past twenty years, these techniques have been considerably further developed and extended to include the use of the polymerase chain reaction (PCR), which now plays a major role in the manipulation of DNA. These methods enable many proteins from a variety of sources (e.g., human, yeast, bacterial, and archaeobacterial) to be produced in large quantities in bacteria,

generally *Escherichia coli*. This greatly facilitates the process of obtaining sufficient quantities of pure proteins for biophysical analysis. Further, these technologies allow one to engineer proteins with ease by modifying the genes (DNA) that encode for a specific protein. A number of different methods of engineering proteins can be adopted: site-directed mutagenesis can be used to replace one amino acid in a protein with any other at a specific position in the protein thereby producing a mutant protein with a single mutation (the protein with the naturally occurring sequence is known as the “wild type”). Alternatively, multiple mutations can be made either rationally or randomly; the latter is a powerful technique when combined with a selection screen for proteins with a particular property. Proteins can also be changed more radically in a variety of ways, for example, by changing the order in which structural units or motifs are connected, resulting in a mutant protein which has the same overall structure as the wild-type protein but with different connectivities between structural subunits. These mutant proteins are known as circular permutants. These methodologies are now routine and used widely by the protein-folding community. A review of the entire field is beyond the scope of this article. Here, the focus is primarily on the results that have come from single-site-directed mutagenic studies, which have had the biggest impact on the field of protein folding. In particular, the focus is on the methods of analyzing protein-folding pathways using protein-engineering approaches and the models that have resulted from such work.

Characterizing Folding Pathways: φ -Value Analysis

In order to understand how proteins fold, the structure and energetics of all states on the folding pathway need to be characterized. This includes the folded or native state, the unfolded or denatured state, as well as any intermediate states. Whereas, in the early years of protein folding it was thought that stable intermediate states were a prerequisite enabling the protein to fold on physiological timescales by reducing the amount of conformational space that needed to be sampled, in the early 1990s it was shown that a small protein, CI2, could fold very rapidly indeed without populating any such partially structured states. It is now well established that many small proteins fold in this so-called “two-state” fashion. In these cases, and others, one of the most important states to characterize on the folding pathway is the rate-limiting transition state which represents the energetic barrier to folding. Whilst the unfolded and folded states can be characterized directly using X-ray crystallography and multidimensional NMR techniques, the structure and energetics of the transition state can only be inferred from kinetic measurements. Fersht and co-workers have developed a method for analyzing folding transition states which is known as φ -value analysis and which uses protein-engineering approaches. The method is outlined below.

A point mutation is made to a protein and the kinetics of folding and unfolding are measured for both the wild-type protein and the mutant. In general, “nondisruptive deletions” are engineered such that the mutation removes a single interaction in the folded state of the protein and does not introduce any new interactions. In these cases, interpretation of φ -values is straightforward. The mutations usually destabilize the native state of the protein with respect to the denatured state (Figure 1). $\Delta\Delta G_{D-N}$ is the difference in the free energy of unfolding (the energy difference between D, the denatured state, and N, the native state) between the wild type and the mutant, and a positive sign indicates that the mutation is destabilizing. It is straightforward to measure this difference under equilibrium conditions using a suitable probe of the folded state, frequently intrinsic fluorescence of aromatic amino acids or far-UV circular dichroism. In order to quantitate the effect of a mutation on the transition state for folding, then $\Delta\Delta G_{\ddagger-D}$, the energy difference between the transition state ($\ddagger$) and the denatured state, between the wild type and the mutant, also needs to be measured (Figure 1). For simple systems, such as CI2 which fold in a two-state manner, this value can be calculated from the unfolding data (by measuring the rate constant of unfolding, k_U , which is determined by the energy barrier for unfolding), or from the folding data using the rate constant for folding, k_F . A φ -value is defined as the ratio of $\Delta\Delta G_{\ddagger-D}$ to $\Delta\Delta G_{D-N}$, which is a measure of the extent to which favorable interactions that the side chain of the mutated amino acid makes in the native state are formed in the transition state. Formal definitions of the different parameters are given below. Unfolding data can be used to calculate φ -values whether folding is two-state or not, as for small proteins no intermediate states are stable under unfolding conditions

$$\Delta\Delta G_{\ddagger-N} = -RT\ln(k_U/k'_U) \quad [1]$$

where k_U and k'_U are the rate constants of unfolding for the wild type and mutant, respectively. In this case, a φ -value is defined as follows:

$$\Phi = 1 - \Delta\Delta G_{\ddagger-N} / \Delta\Delta G_{D-N} \quad [2]$$

For those small proteins that fold with two-state kinetics, φ -values can also be calculated from folding rate constants

$$\Delta\Delta G_{\ddagger-D} = -RT\ln(k_F/k'_F) \quad [3]$$

where k_F and k'_F are the rate constants of folding for the wild type and mutant, respectively.

In this case, a φ -value is defined as follows:

$$\Phi = \Delta\Delta G_{\ddagger-D} / \Delta\Delta G_{N-D} \quad [4]$$

For two-state systems, φ -values calculated from the unfolding and folding data are the same.

Figure 1 Free-energy diagrams showing the effect of a destabilizing mutation on the energy of the denatured (D), transition ($\ddagger$), and native (N) state of a protein which folds with simple two-state kinetics. Case 1, when $\Delta\Delta G_{\ddagger-D} = \Delta\Delta G_{N-D}$ then $\phi = 1$. In this case, the mutation affects the folding rate but not the unfolding rate – see the “chevron” plot of the rate constants for folding/unfolding as a function of denaturant concentration (right-hand side of figure). At low concentrations of the denaturant, the folding rate constant is measured and this decreases exponentially with increasing denaturant concentration, whilst at high concentrations of the denaturant, the unfolding rate constant is measured and this increases exponentially with increasing denaturant concentration. Case 2, $\Delta\Delta G_{\ddagger-D} = 0$ then $\phi = 0$. In this case, the mutation affects the unfolding rate but not the folding rate. Case 3, $0 < \Delta\Delta G_{\ddagger-D} < \Delta\Delta G_{N-D}$ then $0 < \phi < 1$. In this case, the mutation affects both unfolding and folding rate constants. (Reprinted with permission from Daggett V and Fersht AR (2003) The present view of the mechanism of protein folding. *Nature Reviews. Molecular Cell Biology* 4: 497–502; © Macmillan Magazines Ltd.)

Interpretation of ϕ -Values

Briefly, $\phi = 1$ when $\Delta\Delta G_{\ddagger-D} = \Delta\Delta G_{N-D}$, that is, the lost interaction energy upon mutation is the same in the native and transition states (Figure 1, case 1). In this case, the mutation affects only the rate of folding and not the rate of unfolding. ϕ -Values of 1 occur when the transition state is highly structured in the region of the mutation. Conversely, $\phi = 0$ when $\Delta\Delta G_{\ddagger-D} = 0$, that is, when the mutation has no effect upon the energy of the transition state relative to the unfolded state (Figure 1, case 2). In this case, the mutation affects the rate of unfolding but has no effect on the rate of folding. ϕ -Values of 0 occur when the transition state is completely unstructured in the region of the mutation. Besides the values of 0 and 1, fractional ϕ -values are obtained when $0 < \Delta\Delta G_{\ddagger-D} < \Delta\Delta G_{N-D}$ (Figure 1, case 3). In this case, the mutation has an effect on both unfolding and folding rate constants. In general, fractional ϕ -Values are more difficult to interpret; however, in some cases, there is an approximately linear relationship between the ϕ -Value and the extent of formation of nonpolar contacts in the transition state relative to the native state. In these cases, ϕ -values are a good measure of the degree to which interactions of the mutated side chain are made in the transition state. An extensive description of the interpretation of ϕ -values and the assumptions and limitations of this method are not within the scope of this article and are discussed in detail elsewhere; see “Further reading.”

In order to illustrate this method, the results of protein engineering and ϕ -value analysis on the small protein FKBP12 from the author’s laboratory are discussed briefly below. FKBP12 is a small protein, the structure of which is shown in Figure 2a. Extensive

Figure 2 (a) Structure of the small, 106-residue protein FKBP12. Shown in red is the single α -helix, shown in green are the five β -strands which wrap around the helix to form the hydrophobic core. (b) Results of protein engineering studies and ϕ -value analysis. ϕ -values range from 0 (blue) to 0.6 (red). The side chains of the mutated residues are shown. (c) View of the ϕ -values and structure of FKBP12 rotated through 90° . protein engineering was performed on FKBP12 and the effect of mutations on the stability and kinetics of folding and unfolding of the protein was measured. Data were analyzed by the method described above and ϕ -values for many residues in the protein obtained. The results of these studies are summarized in Figures 2b and 2c, which show the range of ϕ -values obtained and regions of the protein that have high values (are partially structured in the transition state) and those that have very low values (regions which are largely unstructured in the transition state). As expected, the ϕ -values vary between 0 and 1. In the case of FKBP12, no values of 1 were found, the highest value being 0.6. This is quite typical for small proteins. From Figure 2, it can be seen that residues with high values (>0.5) cluster together and form a folding nucleus (see discussion on nucleation–condensation mechanism). In FKBP12, the nucleus is formed by residues at the C-terminus of the α -helix and residues in the middle of the central β -strands which form part of the hydrophobic core. There is a gradation of ϕ -values moving away from this nucleus, and edge strands and end of the β -strands and loop regions frequently have values close to zero indicating that these regions are highly flexible and unstructured in the transition state. FKBP12 behaves in many ways like other small proteins including CI2 (see next section).

The resolution with which folding pathways can be determined using this approach has meant that it is now the most popular way of characterizing folding transition states experimentally and ϕ -values have now been measured for a number of proteins. Results from these studies from numerous folding groups fall broadly into one of three categories illustrated by the three examples given below. Together, these studies give a detailed picture of the ways in which proteins fold.

CI2 Protein-Engineering Results: The Nucleation–Condensation Mechanism

As discussed above, the small protein CI2 folds in a simple two-state manner without populating a stable intermediate state. Thus, mechanisms which require a stable intermediate to be present cannot be applied to this protein. Protein-engineering experiments have mapped in detail the structure of, and interactions present in, the transition state. As a result of these studies, the nucleation–condensation mechanism of protein folding was proposed by Fersht and co-workers in the mid-1990s. In this mechanism, the rate-limiting step of folding is the formation of a folding nucleus which can either involve a large part of the protein structure (in this case, the protein is said to have a diffuse nucleus) or comprise just a few elements of secondary structure (in this case, the nucleus is said to be localized). After the nucleus has formed, folding involves the rapid condensation of the rest of the native structure around the nucleus in an energetically downhill process. For CI2, the nucleus is quite diffuse, involving, to some degree, most regions of the protein. However, several residues in the α -helix and in the β -sheet are the most critical in stabilizing the transition state structure. In contrast to earlier proposed mechanisms, in the nucleation–condensation model, secondary and tertiary structures are formed concomitantly, the secondary structure being inherently unstable without the presence of some stabilizing tertiary interactions. NMR spectroscopy and molecular dynamic simulations have both shown that the denatured state of CI2 has little fixed structure and approximates well to a random coil. The complete folding pathway of CI2 is shown in Figure 3a.

Barnase: Hierarchical Folding Mechanisms

Barnase was the first protein to be subject to an extensive protein engineering and ϕ -value analysis and its folding pathway illustrates some key differences with CI2. Barnase is a larger protein, 110 residues in length, which, in contrast to CI2, folds with three-state kinetics demonstrating the presence of a kinetically significant, populated, intermediate state on the folding pathway. A close

Figure 3 Schematic representations of the folding pathways of (a) CI2, (b) barnase, and (c) engrailed homeodomain. Results from protein-engineering studies and molecular dynamic simulations. (Reprinted with permission from Daggett V and Fersht AR (2003) The present view of the mechanism of protein folding. *Nature Reviews. Molecular Cell Biology* 4: 497–502; © Macmillan Magazines Ltd.)

analysis of the native structure of barnase shows that it has two structural subdomains. In contrast with CI2, barnase has a significant residual structure in the denatured state as probed by molecular dynamics simulations and NMR spectroscopy, that is, the denatured state is not a random coil and elements of both secondary and tertiary structure are transiently formed in this state. In barnase, the residual structure establishes a loose native-like topology in the denatured state which facilitates folding. From this state, the main hydrophobic core of the protein folds via a nucleation–condensation mechanism similar to CI2. The folding is nucleated by a residual fluctuating native-like helical structure in α_1 with a β_3 – β_4 hairpin. The α_1 , β_3 , and β_4 elements of secondary structure form a scaffold or nucleus on which the remaining β -strands pack. This creates the metastable intermediate state observed in the kinetics. Further collapse and consolidation then occurs which brings residues involved in stabilizing the rate-limiting transition state together. During the formation of this nucleus, there is a refinement of packing interactions and consolidation of the interface between the two structural subdomains. Thus, barnase shows more hierarchical folding than CI2, with a gradual build-up of structure along the folding pathway. A schematic representation of the folding pathway of barnase is shown in Figure 3b.

Ultrafast Folders: The Engrailed Homeodomain

CI2 and barnase fold on the order of milliseconds to seconds at room temperature. Recently, proteins which fold with much faster rates have been identified and their folding pathways characterized using the techniques described above. The engrailed homeodomain from *Drosophila melanogaster* (En-HD) is a 61-residue, highly helical protein which folds on the microsecond timescale under physiological conditions. When unfolded in high concentrations of chemical denaturant or at very high temperatures, the unfolded state contains rather little residual secondary structure which is highly dynamic and fluctuating. Under more physiological conditions, however, at lower temperatures in the absence of denaturants, the denatured state has considerable residual structure with a high helical content and some long-range tertiary contacts. Combining experimental protein-engineering results with molecular dynamic simulations has provided a detailed picture of how this protein folds, Figure 3c. From the physiological denatured state (D), the transition state ($\ddagger$) is formed by a reorientation of the helices and docking of them to form a partially packed hydrophobic core. In the final steps, the helices fully dock against each other and water is expelled from the hydrophobic core. En-HD folds by first forming relatively stable elements of secondary structure (in this case α -helices) which then diffuse and collide to form the tertiary structure and the native state. This is much like the framework model proposed by Ptitsyn and co-workers in the early days of protein folding.

A Unifying Mechanism?

Outlined above are the results of detailed experimental and computational studies on the folding pathways of three proteins. These three proteins are excellent examples illustrating the different mechanisms by which proteins can fold. It is useful to include a short history of the field of protein folding here, to show how recent work has established new folding mechanisms and shed light on mechanisms which were proposed in the early days of the field when high-resolution structural information on folding pathways was not yet available. The Holy Grail of folding is, of course, to unite these different mechanisms into a simple single mechanism applicable to all proteins. This unified mechanism is presented later after a brief discussion of individual mechanisms.

Wetlaufer was one of the first to propose a nucleation type of mechanism, that of nucleation growth, back in 1973. Here, an initial nucleus of local secondary structure forms and then the tertiary structure propagates rapidly from this. As this mechanism does not require the formation of stable intermediate states – and at that time all experimental studies were focused on proteins which folded slowly and had discrete intermediates (later some of these intermediates were shown to be misfolded species off the main folding pathway) – the nucleation-growth mechanism was not widely adopted. At that time, experimental studies were limited by suitable experimental techniques and rapid-reaction kinetics had not yet been applied to complex biological problems such as protein folding. In addition, protein engineering was still in its infancy. Other mechanisms were proposed and dominated in the 1970s and 1980s: the framework model in which secondary structure folds first, then diffuses and collides to form the three-dimensional native structure; the hydrophobic collapse model, in which the hydrophobic effect drives the formation of a compact state in which many hydrophobic side chains are excluded from the solvent water, rearrangement then takes place to form the fully folded structure. This model was extended and it was proposed that a secondary structure was formed during the collapse stage to form a “molten-globule”-like intermediate state. These molten-globule states have a native-like secondary structure but a liquid-like core in which side chains retain a high degree of mobility and in which fixed tertiary interactions are not yet formed. In the early 1990s, and as a direct result of protein-engineering studies and φ -value analysis by Fersht and coworkers on CI2, a new mechanism – the nucleation–condensation model – was proposed.

The results and models of the folding of CI2, barnase, and En-HD are typical of the range of results obtained for the folding of a number of small proteins. Despite apparent differences in the way in which these three proteins fold, Daggett and Fersht have recently proposed a unified mechanism of folding based on the nucleation–condensation model. In their view of folding, there is a spectrum of pathways available to a protein with the framework mechanism at one end of the spectrum and the hydrophobic collapse model at the other. The nucleation–condensation mechanism lies in the center of this spectrum and the two other models can be viewed as extreme cases. Proteins which have sequences with high intrinsic propensities for forming stable elements of secondary structure, such as the engrailed homeodomain, tend to fold with mechanisms which lie at one end of the spectrum and which approximate to a framework model. Proteins for which the conformational preferences for secondary structure are weak, such as CI2, tend to fold according to a nucleation–condensation mechanism in which secondary structural elements are stabilized by tertiary interactions in the transition state. Larger proteins with more than one structural subdomain, such as barnase, fold in a hierarchical fashion but each subdomain, however, folds with a mechanism which lies somewhere on the spectrum of mechanisms found for smaller proteins. It is interesting that, although the hydrophobic collapse model can be viewed as one extreme of the folding spectrum, there are no examples so far of small proteins which fold in this way. Theoretically, proteins may fold through a molten-globule-like intermediate if hydrophobic interactions are very strong.

Computational Approaches

It is clear from the discussions on CI2, barnase, and En-HD given above that results from computational studies in conjunction with experimental results of φ -values from protein-engineering studies have played a critical role in the development of new folding mechanisms and in increasing our knowledge of the complexities of the energy landscape for folding of small proteins. Although it is beyond the scope of this article, a few words on the main computational techniques used are included here. Many different computational approaches have been employed in the 1990s and applied to the protein-folding problem. These approaches range from rather coarse-grained models in which amino acids in the polypeptide chain are treated as beads on a string, a lattice-based structure is used, and simple pairwise potentials are employed. At the other end of the scale, all-atom molecular dynamic approaches have also been widely applied to the protein-folding problem. The different approaches, limited in different ways, have provided very complementary information on folding mechanisms and the fundamental questions regarding folding. Simple models and lattice-based approaches have provided support for nucleation-based mechanisms of folding, as well as being used to investigate cooperativity in folding. All-atom MD simulations are the most realistic of computational approaches but are restricted by the computational power and time necessary to simulate complex biological systems such as proteins (10000 plus atoms). With the exception of small structural motifs, such as β -hairpins, for which folding has been simulated using distributed computing techniques, simulations of folding itself are not possible. This problem has been circumvented by simulating unfolding processes using high temperatures to accelerate the unfolding event. In these cases, the potentials used correspond to lower temperatures, the effect of the high temperature merely being to speed up the process but not change the mechanism. Using the principle of microscopic reversibility, the unfolding and folding pathways must be identical under the same conditions. Thus, it has been possible to gain information on folding pathways using these techniques. Rigorous testing of this approach has been performed

with multiple simulations of the same protein under different temperatures and conditions. Results of this type of testing have shown the technique to be robust. Further, this type of approach has now been benchmarked extensively against experimental data and shown to be reliable and accurate in predicting experimental results. From these simulations, ensembles of structures corresponding to the denatured, intermediate, and transition states have been identified and characterized for a significant number of small proteins. The data obtained from these simulations is very much complementary to that obtained from φ -value analysis, the one generating structures whilst the other provides information on the energetics of the system.

Recently, experimental and computational approaches have been combined and new methods developed by Vendruscolo, Paci and co-workers to probe in further detail the structures of, and interactions in, transition state ensembles. Experimental φ -values are used as restraints in simulations, in a manner similar to the use of NOE data in NMR structure determination, and computational approaches used to generate an ensemble of conformations corresponding to the transition state. The advantage over the MD unfolding simulations described above is that a large number of conformations can be generated rapidly. This approach has been successfully applied to the small 98-residue protein acylphosphatase to characterize the network of interactions that stabilize the transition state and which are formed when a few key residues (the folding nucleus) form a native-like arrangement.

Introduction

The protein folding problem concerns understanding how a protein of specified amino acid sequence ends up in a unique configuration which, among other things, determines its biological function. In physical terms: how does the one-dimensional information provided by the sequence of 20 different types of amino acids encode for a unique and stable three-dimensional equilibrium conformation.

This problem has a clear biological and medical importance. The sequencing of the human genome provides information on the sequence of amino acids forming each of the hundreds of thousands of proteins which build our cells. The acquisition of sequence data by DNA sequencing is relatively quick, and vast quantities of data have become available through international efforts. On the other hand, the acquisition of three-dimensional data is still slow and is limited to proteins that either crystallize in a suitable form or are sufficiently small and soluble so that their structure can be determined by NMR in solution. Algorithms are thus required to translate the linear information into spatial information.

But the protein folding problem is quite intriguing also from a physical point of view. A protein is a system which is in a nearly-zero-entropy equilibrium state (usually referred to as “native” state; cf., e.g., Figure 1) in a wide range of temperatures (typically from 0°C to 60°C). Such equilibrium state has essentially no symmetries. The interactions within the protein are noticeably complicated and heterogeneous. Nonetheless, the protein does not display, as a rule, any competing low-energy states or kinetic traps (metastable states) typical of “frustrated” systems, but folds on a short call. The only feature typical of frustrated systems that survives in the case of proteins is the difficulty of predicting the ground state conformation from the knowledge of its elements (amino acids) and their interaction.

The goal of the physical approach to the protein folding problem is to understand the general principles of the folding mechanism of any protein. This implies that such a mechanism displays some amount of universality. There is indeed evidence that supports this scenario. In fact, aside from displaying a unique state of equilibrium (unique at the length scale of amino acids, i.e., 10^{-10} m) at biological temperatures, most proteins undergo a highly cooperative denaturation when the temperature is increased, similar to first-order phase transition (see Figure 2). The average folding time of proteins usually ranges from microseconds to seconds, and the distribution is usually a single- or multi-exponential, typical of a (or of few) Poissonian process. As a rule, proteins are very tolerant to point mutations. Mutations in a large number of sites have little or no effect on the folding properties of the protein, while each protein displays some key sites which, if mutated, lead to a large destabilization of the native state.

Typical cells contain around 20% proteins by weight. Consequently, evolution has provided proteins not only with the ability to fold on their own, but also to avoid aggregation, or to recognize other amino acid chains to perform their biological task. As in the case of oligomers, ordered assemblies of few single chains, which display the same features of unicity, stability, and fast folding of monomeric proteins.

Models for Folding

The simplest (and oldest) interpretation of the folding process consists of summarizing all possible conformations in a few macroscopic states, in the same way as is done to describe chemical reactions. Usually, the thermodynamically relevant states are the unfolded states (U), which contain all the conformations where the protein chain is unstructured; the native state (N), which corresponds by definition to a single conformation; and possibly some intermediate states ($I_1, I_2, \dots$). The folding reaction is thus viewed as a chain of events $U \rightarrow I_1 \rightarrow I_2 \rightarrow \dots \rightarrow N$, and the dynamics of the associated probabilities is described by a mean of master equations. The distribution of folding times results in a sum of a number of exponential terms of the type $e^{-t/\tau}$ equal to the number of jumps between states that the system has to do to reach the native state. The typical time τ needed to perform each of such jumps is determined, according to Kramer's theory, by the height of the free-energy barrier ΔF , which separates the two states, and has the form $\tau \propto \exp[\Delta F/kT]$. In the case of small globular proteins, experiments often detect a single timescale for folding, indicating a two-state process between states U and N .

Figure 1 The native conformation of chymotrypsin inhibitor 2. The light gray parts highlight the arrangement of the atoms, which build a complicated network of interactions. In dark gray is highlighted the backbone of the protein.

Figure 2 The typical free-energy landscape of a protein, plotted with respect to an arbitrary reaction coordinate x . Although the complexity of the interactions leaves some roughness in the landscape, evolution has shaped it in order to display two major wells separated by a barrier. The minimum associated with the native state (N) has essentially zero entropy and is stabilized by its attractive interactions, while the unfolded state (U) is mainly stabilized by its large entropy. As a consequence, when the temperature is increased, the free energy of the unfolded state decreases stabilizing it.

This simple model highlights the cooperativity of the folding process, determined by the presence of a major free-energy barrier, and provides good numerical estimates for the dependence of folding times on temperature and on mutations in protein sequence, but provides little insight into the molecular aspects of folding.

More recently, the focus has moved towards understanding the protein folding mechanism through a detailed description of the associated free energy landscape. A model which pursues this goal (the Go model) describes realistically the geometry of the protein but makes use of a simplified two-body potential function. Starting from the knowledge of the native conformation of the protein, two atoms are defined to be in (native) contact if their distance is smaller than a threshold. To such a conformation is ascribed a (negative) energy, and zero otherwise. This model, used in connection with computer simulations, is aimed at approximating the free energy with a careful entropic part and a simplified energetic part. Studying the folding of a number of small globular proteins with the help of the Go model, it is observed that the conformations associated with the top of the free-energy barrier separating the unfolded from the native conformation have well-defined structural properties, characterized by some important native contacts.

A different approach focuses attention on the energetic content of the free-energy function and, in particular, on the heterogeneity of the interaction arising from the presence of 20 kinds of different amino acids. It is known that physical systems displaying such a heterogeneity are associated, as a rule, with a rough energy landscape with many competing low-energy states. This picture is incompatible with that of proteins, which must display a unique ground state, well separated from the others, and as few metastable states as possible. The purpose of these models is to understand what makes a protein, characterized by a well-defined amino acid sequence, different from a generic heterogeneous system, whose paradigm is a random sequence of amino acids.

The starting point of energy-based models is the study of the thermodynamics of a random heteropolymer, which is an idealization of the peptide chain only characterized by stochastically independent contact energies. Being the sum of independent stochastic contributions, the total energy of the heteropolymer follows a Gaussian distribution, according to the Central Limit Theorem. Identifying this distribution with the distribution of conformational energies of the heteropolymer, the number of conformational states as a function of energy is

$$n(E) \propto \exp \left[-N_c \left(\frac{(E - N_c \varepsilon_0)^2}{2N_c^2 \sigma_\varepsilon^2} - \ln \gamma \right) \right] \quad [1]$$

where N_c is the number of contacts in the chain (assumed to be constant), ε_0 and σ_ε are the mean and the standard deviation over the 20 types of amino acids of the contact energies, and γ is the number of conformations that the chain can build per contact. Similar to the random energy model used in the field of spin glasses, the random heteropolymer model displays an entropy given by the relation $S(E) = N_c \ln \gamma - (E - N_c \varepsilon_0)^2 / (2N_c \sigma_\varepsilon^2)$ at energies above the threshold energy $E_c \equiv N_c \varepsilon_0 - N_c \sigma (2 \ln \gamma)^{1/2}$. On the other hand, below E_c the probability of finding any state of the heteropolymer is negligible, decreasing exponentially with the number of contacts N_c . Using the replica solution originally set up for spin glasses, it is possible to show that low-energy states are clustered in such a way that different clusters are separated by an energy barrier. This is a picture which can be hardly conciliated with that of proteins displaying a unique equilibrium state.

This simple model emphasizes a property of peptidic chains, that is the “frustration” due to the complicated interaction between 20 amino acids with different physical properties. “Frustration” implies the inability the system has to optimize all interactions at the same time, even in the lowest-energy state. A sequence of amino acids chosen at random is likely to be highly frustrated, and consequently not to display protein-like features. Within such a scenario, it is assumed that evolution selects protein sequences by minimizing the associated frustration. Setting this scenario within the framework of statistical mechanics, one can assume that protein-like sequences are those which display in some conformation an energy much lower than the sequence-independent threshold E_c , this conformation being the native state. In fact, if the native state is well below E_c , it does not have to compete with the other conformations whose energies are controlled by eqn [1]. Consequently, the native state will be unique and stable, more so, the larger the energy gap between the native state and E_c .

From the study of the models described above it emerges that the key ingredients of proteins to fold are their polymeric character and the heterogeneity of interactions. A powerful tool which allows to retain these two ingredients, although relaxing that of providing a detailed description of the protein geometry, is the lattice model. This model is based on two approximations: (1) the internal atomic structure of the amino acids is neglected and each of them is described as pointlike; (2) the amino acids move on the vertices of a cubic lattice of unitary side length. Accordingly, the conformational degrees of freedom are discrete. This is very convenient from a computational point of view and makes conformational entropy easy to handle, provided a contact potential is given. The simplest choice of such a potential has the form

$$U(\{r_i\}, \{\sigma(i)\}) = \sum_{ij} \varepsilon_{\sigma(i)\sigma(j)} \Delta(r_i - r_j) \quad [2]$$

where r_i and $\sigma(i)$ are the position and type of the i th amino acid, $\Delta(r_i - r_j)$ being a contact function assuming the value 1 if the i th and the j th amino acids are in contact and zero otherwise, while $\varepsilon_{\sigma\tau}$ is the element of a 20×20 interaction matrix which measures the interaction energy between amino acids of type σ and τ . A widely used interaction matrix has been determined by Miyazawa and Jernigan from the statistical analysis of the contacts of a large database of proteins, assuming that the frequency with which a given contact appears in the database measures the strength of the contact energy between the corresponding amino acids.

Within the framework of the lattice model, it is possible to obtain a data set of sequences which fold into a selected native conformation starting from a random sequence displaying the observed composition (experimental ratio of the different types of amino acids), by swapping amino acids in such a way as to minimize the energy of the protein in the native conformation. This is a consequence of the fact that E_c does not depend on the details of the sequence, but only on its length. In other words, swapping amino acids does not change E_c , while the native energy can be decreased until it displays a large gap with respect to E_c .

A key result which emerges from such studies is that the stabilization energy of the protein is not distributed evenly throughout the native conformation, but is concentrated in a few, “hot” sites. This fact has remarkable consequences on the properties of the protein. First, it sheds light on the experimental fact that a protein is essentially insensitive to mutations in most of its sites. In fact, if a site different from the few “hot” sites is mutated, the change in native energy is not enough to fill the gap to the threshold energy E_c (which is not affected by the mutation), and consequently the protein retains its protein-like features. On the other hand, if a “hot” site is mutated, the energy of the resulting sequence in the native conformation can become larger than E_c . Consequently, the native state gets surrounded by a sea of unfolded conformation, losing its uniqueness.

Moreover, lattice model calculations indicate that “hot” sites build, as a rule, local elementary structures (LEs), that is fragments of the chain characterized by strong interactions between the “hot” sites which are close along the chain. Such LEs, which can be viewed as hidden, incipient secondary structures (like beta-sheets and alpha-helices) are very important for the folding dynamics

because they bias the chain to the native state, according to a hierarchical scheme. Starting from a random conformation, LESs are formed very fast, because their stabilizing native contacts are close along the chain and, consequently, they do not need to explore a wide conformational space. Due to their large stabilization energy, LESs remain remarkably stable for the whole folding process. The rate-limiting step is then that of the assembly of LESs among themselves to build out their relative native contacts (the so-called “folding nucleus”). Being (quasi-) rigid entities, LESs make the chain effectively shorter. Furthermore, LESs interact among themselves with energies which are much larger than those with which single amino acids do. Consequently, it is unlikely that LESs form metastable structures, different from the native contacts designed by evolution. Once LESs have reached their mutual native positions, the conformational space of the protein is so restricted that the remaining amino acids fold immediately to their native position. Summing up, LESs provide an efficient way to squeeze out entropy from the initial random conformation in its way to the native state, avoiding metastable traps.

The uneven distribution of the stabilization energy and some hints about the events which take place on the folding trajectories of small real proteins can be studied by means of all-atom molecular dynamics simulations, combined with semi-empirical force fields. Results of such simulations, performed by considering specifically water, reveal the existence and allows the identification of “hot” sites. However, the simulation of the complete folding trajectory and the repetition of such simulations to obtain a statistically significant sample of the event is still computationally out of reach.

Aggregation

The term “aggregation” can mean a number of different processes, when applied to proteins. The simplest case is that of dimerization (or oligomerization), where two (or few) amino acid polypeptide chains assemble together into a conformation which displays all properties typical of the native state of monomeric proteins (e.g., uniqueness, stability, etc.). There are essentially three paradigms for this process. The best-understood is that of “exchange-domain” dimers, wherein two identical proteins have been induced by evolution to exchange part of their peptidic chain, giving rise to an intertwined, symmetric conformation. The “lock-and-key” scenario is followed by those chains which first fold into monomeric native states and then assemble together, resulting at equilibrium in three populated states: denaturated, intermediate (single chain folded), and oligomeric (dock of single folded chains). On the other hand, “induced fit” oligomers first bind together in an unstructured conformation and subsequently find the native structure. While dimers (or oligomers) following the “exchange-domain” and the lock-and-key mechanism can still be described in terms of a few key sites (hot sites) controlling the whole process as in the case of single domain proteins, the “induced-fit” mechanism seems to be more subtle, implying a delicate balance between the contact energies at the interface and in the volume.

A mechanism similar to the lock-and-key mechanism can be used at larger scales, giving rise to micrometric, ordered structures. It is the case of tubulin, which builds microtubules in the cell, and actin, which builds muscle fibers. Aggregation can involve, under particular conditions, also proteins which usually fold to monomeric native conformations.

A cell contains 17–26% of proteins by weight, and in the cytoplasm there are $\sim 10^6$ peptide chains, separated by an average distance of 3 nm. It is thus likely that evolution has selected sequences not only to fold on their own, but also to avoid the interference of other proteins. Nonetheless, mutations, changes in the chemical environment, or other factors can make proteins aggregate into (usually) biologically inactive, eventually harmful, clumps.

Aggregates can be disordered clumps, kept together by unspecific interactions, or an ordered, elongated structure usually called a fibril (see Figure 3). There is strong evidence that a number of diseases are related to the deposit of fibrils in particular areas of the

Figure 3 Fibrils made of insulin detected by atomic force microscopy. The length scale of the figure is μm .

human body (e.g., fibrils of beta-amyloid protein in the brain, in the case of Alzheimer's disease). Solid state NMR experiments have shown that, as a rule, fibrils contain parallel arrangements of specific U-like conformations of parts of the protein.

Aggregation is usually triggered by a nucleation event, and consequently the whole process can be separated into formation of the nucleus, that is, the minimum stable aggregate, and growth. Nucleation is a mechanism which reflects the entire thermodynamics of the solution, affected by the thermodynamic fluctuations of the solvent. For example, it has been shown that nucleation rate of sickle cell hemoglobin is strongly dependent on fluctuations associated with liquid-liquid demixing phase transition. Nucleation can be slowed down by stabilization of nonaggregating metastable states: light-scattering experiments and models based on molecular dynamics simulations indicate that micelle-like structures composed of a few beta-amyloid monomers compete with nuclei and discourage fibril formation. Also, the growth process often involves a nontrivial process which goes beyond mere diffusion. For example, the rate of elongation of beta-amyloid fibrils depends on temperature following an Arrhenius law, indicating that the binding of monomers to the end part of a fibril requires conformational changes.

Introduction

Activities of life on Earth are carried out by proteins, which are synthesized according to the genome of the organism. A protein is a kind of molecular nanomachine, which takes an important role in biological functions such as (i) signal transduction, (ii) molecular recognition, (iii) catalyzing enzymatic reactions, and (iv) transporting molecules, ions, and electrons. Although the size of an individual protein molecule is typically several tens of nm, proteins form various structures that correspond to their inherent nature and the surrounding environment. Moreover, they cooperatively act on each other to maintain life. To understand their biological functions, one of the most important keyword is 'structure–function relationship'; this indicates that a particular protein has its native structure in physiological conditions, which enables it to carry out a certain function in those conditions. Thus, knowing the structure of a protein is essential to understanding the mechanism of its functionalities.

Since Kendrew and Perutz determined X-ray structures of myoglobin (1958) and hemoglobin (1960), both X-ray crystallography and nuclear magnetic resonance (NMR) experiments have so far described about 110 000 proteins at atomic resolution (Aug 2015). These structures are deposited in the Protein Data Bank (PDB), which is a convenient and freely available web service. However, the total number of proteins in organisms is thought to be about 10 000 000. Some of them are difficult to crystallize and are too big to have their structures measured by NMR experiments. Recently, electron microscope techniques have enabled measurements of the surface of large protein structures, but these experiments have yet to reach atomic resolution. Thus, it remains important to predict possible structures of proteins and their functions from a given amino acid (AA) sequence. During the last four decades, many theoreticians and experimentalists have worked to reveal the principles of protein-folding processes in nature. However, it is still difficult to do this and it is recognized as a fundamental problem in this field. In this commentary, we focus on giving the basics of the protein-folding problem and surveying both theoretical and experimental progress in the last 10 years.

Basics of Protein Structure

A protein comprises a one-dimensional sequence of 20 different AA residues with no branches. A small one typically consists of several tens of AAs and larger ones contain thousands of AAs, so that they form complicated macromolecular structures that range from 1000 to several hundred thousand atoms. Several subunits of the protein sometimes combine to form a complex of proteins. Moreover, some proteins contain small molecules, atomic groups, and ions as cofactors inside their structures to support complex structures and functions. For example, photosystem I (PS I) is a gigantic protein complex that consists of 11 subunits: [FeS] clusters, chlorophylls, β -carotenoids, phylloquinones, and so on. In PS I, a special pair of chlorophylls first harvest photon energy, then electron transfer occurs among [FeS], the other chlorophylls, β -carotenoids, and phylloquinones to promote reduction at the active site, a ferredoxin.

[☆]*Change History:* July 2015. Y. Shigeta, R. Harada, and Y. Inagaki made updates to the text and references. A new figure showing a folding funnel and structural changes was added.

In physiological conditions, a protein forms a steric structure according to its AA sequence. In the water-soluble proteins, polar and hydrophilic AAs are largely populated at the surface, while hydrophobic ones are inside the protein. Except for proline, the backbone structure formed by the AAs, $-(O=C)-C\beta-(NH)-$, is the same, so that some common structures are expected to appear in proteins. Indeed a helical structure is called an α -helix and a sheet-like structure a β -sheet, which are generally called the secondary structures. For these structures, a ϕ - ψ plot of the backbone, which is often called a Ramachandran plot, indicates that these angles are extensively populated at specific regions, meaning it should be possible to predict protein structures, because these are not completely random. However, in actual proteins, these secondary structures are linked with loop regions and are three-dimensionally packed with particular alignments. These alignments are called 'folds' and there are tens of thousands of them. It should be noted here that different AA sequences occasionally adopt the same secondary structures and folds.

Early Studies on Protein Folding

In the 1960s, Anfinsen performed a refolding experiment using a ribonuclease A (RNase), where the RNase was initially reduced by β -mercaptoethanol to cleave disulfide (S-S) bonds. It was then denatured by concentrated urea solution to completely lose its native structure, and then the solution was diluted to the physiological condition to yield a reconstructed RNase that was indistinguishable from the native RNase. This landmark experiment led to a dogma: 'the native structure of the protein is uniquely determined by the corresponding AA sequence and is thermodynamically the most stable structure.' This dogma gives a thermophysical background to the protein-folding processes, and it has been supported widely by researchers in protein science. On the other hand, Levinthal proposed a thought experiment for the protein-folding dynamics. If a completely random-coil (unfolded) structure reaches the native structure randomly, it would require a longer time than the age of the universe, meaning that the protein-folding process may use unique routes (Levinthal's paradox). On the basis of these ideas, many experiments were performed to find a two-state transition pathway from the random coil to the native structures. It was proven that relatively small proteins could fold rapidly with no intermediate states. On the other hand, some proteins consisting of more than 100 AAs slowly fold to the native structures via intermediate states called molten globule states. In a molten globule structure, the secondary structures and their folds are quite similar to the natural ones, although they lack particular three-dimensional tight packings among side chains compared with the natural ones. These processes are well explained by the frame model, in which: (a) the secondary structure first forms rapidly to reduce hydrophobic regions' exposure to the aqueous solution, then (b) the secondary structures are aligned because of the long-range interactions among them, and finally (c) after the folds are fixed, fine adjustments among neighboring AAs occur to reach the native structure. However, the framework model does not always hold for all the protein-folding processes. For example, β -lacto-globulin, which is one of the whey proteins in cow's and sheep's milk, first forms several α -helices to become an intermediate state, and then the α -helices gradually collapse to reform the β -sheet-rich structure. These secondary transitions are occasionally found in a growth process of amyloids, and so might be a common process in protein folding.

From theoretical considerations, Go first applied a lattice model for the protein-folding problem and derived a consistency principle: the protein folds to the native structure because of a total, consistent balance of interactions among AAs. The lattice model and its variants are commonly called the Go Model. Later, Wolynes proposed a principle of minimal frustration, which is an expansion of Go's consistency principle and states that the native structure has minimal frustration in interactions among AAs. Following these pioneering studies, the basic picture of the protein-folding process is now based on the existence of the folding funnel proposed by Onuchic, in which the energy landscape from the random-coil structure to the native one consists of downfolding

Figure 1 Schematic view of folding and corresponding folding structures.

with many local minima and the native structure is the global minimum in the landscape, resulting in spontaneous folding to the native structure (Figure 1). Because the free energy is the sum of entropic and enthalpic (potential energy) contributions, the relative stability of the random-coil and natural states is regulated by the competition between the two contributions. The random-coil state has various conformations with high potential energy, whereas the native one has a few conformations with the lowest potential energy, indicating the former is entropically and the latter is energetically favorable. Additions of denaturants and salts, changes in pH, concentration, and temperature, and so on cause changes in the relative stabilities among states, i.e., a change in the energy landscape, which sometimes leads to protein denaturation or an aggregation of proteins.

Complexity of the Protein-folding Problem

The history of the AA sequencer began when Edman established a sequential degradation technique from the N terminus of a given protein in 1950. In 1967, the first automated AA sequencer was described. Since 1990, analyses of complicated structures with posttranslational modifications have been achieved. Nowadays the process is quite fast and highly sensitive in determining the one-dimensional AA sequences. In spite of the availability of the AA sequence, as mentioned before, it is still difficult to predict the three-dimensional structure, even for small fast-folding proteins. Although secondary structures, such as α -helices and β -sheets, can be predicted from parts of a given AA sequence to some degree, a prediction of a fold is far from possible, except for special cases such as an α -bundle or a TIM barrel, because the long-range interactions among regions of AAs simultaneously affect the whole structure and both loop regions and side chains restrict alignment of these secondary structures.

The difficulty of predicting folds causes serious problems, because a fold occasionally affects the secondary structure. For example, two different mutants of a G protein, where 11 AAs consisting of an α -helix or a β -sheet in a part of the wild-type (WT) structure are replaced by the same sequence of 11 AAs, have the same fold as the WT, meaning that the same AA sequence takes either the α -helix or the β -sheet, depending on the situation. This kind of AA sequence is called a chameleon sequence. This suggests that the tertiary structure prediction rather than the secondary one is essentially inevitable for solving the protein-folding problem, because one AA sequence does not always correspond to a unique local secondary structure and has high flexibility in the conformational space. Other examples that partly violate Anfinsen's dogma, i.e., a diversity of conformations, are: (a) the same protein has two different structures depending on the crystal packing; (b) some proteins fold by forming a complex with other proteins as intrinsically disordered proteins; (c) molecular chaperons such as the GroEL/GroES complex support the folding of proteins; and (d) the same misfolded proteins aggregate to form an insoluble fibril-like macrostructure called an amyloid. In these ways, the mechanisms of the protein-folding processes are highly likely variable, and both empirical and nonempirical strategies, or mixtures of them, are indispensable for theoretical predictions.

Structure Prediction of Proteins by Empirical and Physical Models

A group of proteins having a close evolutionary relationship with 50% homology in their AA sequences is called a family, while one with 25% homology is a superfamily. Proteins within the same superfamily often share characteristics in their folds. As noted before, even if the AA sequences differ, the folds of two different AA sequences are occasionally the same. According to this heuristic, homology modeling, which considers that matching in individual parts of AA sequences is not important while that in the total AA sequence is, is often adopted for the structural modeling of a given protein, if structures of proteins in the same superfamily are available as scaffolds. After obtaining a rough structure of the given protein by homology modeling, the energy minimization of the modeled structure follows by adding side chains of AA residues, hydrogen atoms, and surrounding water molecules to yield the finer structure. Although homology modeling has succeeded in obtaining possible structures quickly and seems to be powerful, it has several drawbacks. The method can be adopted only when scaffolds (structures of proteins in the same superfamily) are available, and sometimes overlooks important structures for an AA sequence in the superfamily with a low homology. This is a common failure inherent in data-driven structure-modeling methods that require statistically sufficient numbers of samples to reduce the statistical error. At present, highly developed methods such as a template method, a 3D-1D method, and a fragment assembly method, which refer not only to AA sequences but also to known protein structures, have been widely used and some of them are freely available via their web sites.

As an approach to predict the native structure, computational simulations are powerful tools. In particular, molecular dynamics (MD) simulations with physics-based models have been widely used, not only to predict the native structure of a given protein from its AA sequence but also to trace the protein dynamics directly. Furthermore, MD simulations offer deep understanding of the dynamics that are important for biological functions. If the physical-based methods work properly, they provide valuable information beyond bioinformatics as follows: (a) predictions of conformational changes that are relevant to computational drug discovery; (b) understanding of enzymatic catalysis; (c) understanding of how proteins respond to ligand molecules as an allosteric effect; and (d) designing synthetic proteins that have noncanonical AAs. In the study of protein folding, MD simulations are indispensable for obtaining a complete and detailed picture of the mechanisms with atomic-level resolution, beyond the limits of temporal and spatial resolution of experimental techniques. However, there are several issues that must be tackled to achieve useful simulations of protein folding. They are mainly divided into three issues: (a) accurate models (including force fields) for MD

simulations; (b) sufficient conformational sampling for reproducing the protein folding; and (c) robust data analyses for the big data generated by MD simulations as atomic trajectories to unveil the mechanisms of protein folding.

For structural prediction of a given protein, Critical Assessment of Structure Prediction (CASP), is famous for evaluating native structures. CASP is a community-wide, worldwide experiment for protein structure prediction. It has run every two years from 1994 to 2010. In CASP, predictors prepare a candidate for the native structure of a target protein within a few weeks. Herein, it is important that structural information of the target protein should be protected in a double-blind fashion, i.e., neither the predictors nor the organizers know the structure of the target protein when the predictions are made. Predictors use the available time to run their computer programs, which are usually based on protein sequences of known structure as templates. Templates can be found using sequence alignment methods. From CASP1 held in 1994 to the most recent CASP9 in 2010, structural prediction of the native structure of a given protein has gradually improved.

Protein Evolution

Although the basic processes in protein evolution are point mutations of individual AAs in a polypeptide chain, occasionally there are relatively remarkable changes such as insertions and/or deletions of a series of AAs. Moreover, the repetition or fusion of genes results in generating new proteins or the fusion of AA sequences, respectively. These modifications have accumulated over time, so AA sequences of current proteins are often different from those of primitive ones. In structural biology, one discusses protein evolution from the viewpoints of speciation and functional differentiation. The former means the evolution of homologous proteins with the same function but from different species. Studies of them are of great importance in knowing phylogenetic relations of proteins. On the other hand, the latter means the diversity of the proteins by acquiring different functions from the original ones. This kind of differentiation is thought to originate from AA mutations after the gene repetition to diverge into proteins with different functions. These analyses focus on the existing functionalities of proteins. In this review, we give a brief summary of the differentiation of proteins from the viewpoints of the protein structures and folding processes.

Proteins are not polymers that consist of random AA sequences, but are specific AA sequences that have been selected via evolution over a long period. The problem is: how have they been selected? There are two possible scenarios. One is that abiotic biopolymers (polypeptides) were synthesized in a proto-Earth or extraterrestrial environment. Most of those random AA sequences had no folding ability. However, some of them acquired the ability to fold by chance, and then protobionts harnessed them as biomaterials. Accidentally, these proteins helped the protobiont to survive hostile environments, and then the genes for these proteins might have been preserved for their descendants. The second scenario is that there were initially proteins with partial folding activity. The species with favorable functional proteins for existence were selected and handed their genes down to their descendants. Over generations, the proteins acquired proper folding activities with highly efficient functions. Because it is impossible to reproduce the whole evolutionary process that occurred on Earth, it is difficult to prove which hypothesis is correct or whether both of them are wrong. However, for the latter scenario, there is some collateral evidence. Szostak *et al.* succeeded in selecting proteins with Zn-binding activities from a library with random AA sequences. Among these proteins, they also found proteins with folding activity and showed that their crystal structures are quite similar to those of the wild-type versions. This means that they could identify folding proteins on the basis of the Zn-binding activity. Another ground for the latter scenario is that there are many proteins with indefinite structures in a physiological condition. These are the so-called intrinsically unfolded proteins (IUPs) or intrinsically disordered proteins (IDPs). As noted before, IUPs (IDPs) occasionally fold after binding to other proteins. Because they have characteristic AA sequences, a reverse search of their genetic codes was performed for a gene. It was found that about half of the coded proteins in a gene are IUPs (IDPs). They might have abilities to fold during extra-evolutionary processes and be helpful, or might become active to be adapted to other environments. The energy landscape of the IUP (IDP) has rugged and flat structures such that these proteins wander around many local minima (metastable structures). After binding to or interacting with other proteins, the energy landscape drastically changed to allow folding. This feature is quite different from ordinary folding proteins with their funnel-like folding energy landscape.

The next problem is whether the folding speeds of proteins are related to protein evolution. In a theoretical work that dealt with this problem, Gräter and his coworkers analyzed 92 000 proteins and 989 genomes, and showed with a mathematical model that the folding speed of the proteins became faster during the 40 billion years of evolution since life appeared on Earth. According to their results, it is suggested that (a) the folding speeds of proteins have accelerated from Archaea to multicellular eukaryotic organisms, (b) about 10.5 billion years ago, proteins with complicated structures appeared, resulting in a diversity of protein structures, and then folded proteins slowly developed, and (c) independent of alignment size, the folding speed of proteins became faster. One advantage of proteins folding faster is that it precludes their self-aggregation. These results conform well to the second protein evolution process mentioned above.

Recent Topics in Protein-Folding Research

With recent advances in single-molecule observation techniques, special-purpose computers, and the development of fast MD simulation codes, both the experimental and theoretical research in protein folding have made rapid progress over the past two decades. Below, we summarize the remarkable achievements in this field.

A. Recent Progress in Single Protein-folding Experiments

There are several experimental methods for predicting folding structures by experiments. ϕ -value analyses, which were originally developed in bioengineering, could predict a transition structure during a folding process at AA resolution. In this method, several AA mutations are introduced, and then the kinetics of the folding transition are measured for these mutants to evaluate the ϕ -value, which is a measure of the instability of a transition state following the introduction of the mutation. The ϕ -value is also defined as $\Delta\Delta G^+/\Delta\Delta G^0$, where $\Delta\Delta G^+$ and $\Delta\Delta G^0$ are the changes of activation energies and folding stabilization energies between the wild type and a mutant, respectively. Fersht investigated folding processes (transition state structures, kinetics, and so on) of small proteins with a two-state transition. The results obtained were explained well by those obtained using the Go-model. These facts indicate that two-state folding proteins have a funnel-like free energy landscape. As an extension of ϕ -value analyses, Sosnick proposed ψ -analyses, which might detect more structures in the folding processes of ubiquitin than would ϕ -value analyses. In any case, these analyses lack information about the dynamics of protein-folding processes.

To reveal the dynamics of protein-folding processes, fluorescent resonance energy transfer (FRET) experiments on a single free protein have become popular. In this method, two pigments are labeled on both the C- and N-terminals, and the fluorescent signals are measured over an extended time period. The time series of these signals contain information about the conformational dynamics of a given labeled protein from denatured to natural structures and vice versa. There are two experimental techniques used to observe the fluorescence signals. In one, the protein is fixed on an optical substrate, enabling measurements of the fluorescence signals of the single protein for a long time because the translational modes of the protein are rather restricted. However, the results may contain artifacts originating from interactions between the protein and the substrate. The other technique uses a confocal microscope that can reconstruct three-dimensional images of the fluorescence signals with high resolution. Because the residence time of a flowing sample in an observable region is not long term, the most crucial drawback of the latter method is a limitation on the observable time period. Nevertheless, recent developments in trapping the sample allow measurements for a relatively long time. For example, slow folding processes of a yeast cytochrome *c* (more than milliseconds) were observed from a quench signal caused by the FRET from a pigment to a heme. Other single-molecule experiments have also been developed. One of the most important single-molecule experiment technique is a mechanical unfolding induced by an atomic force microscope (AFM), which was first demonstrated by Mitsui, and then applied to a connectin by Rief. After their pioneering works, refolding processes followed by mechanical unfolding were extensively investigated.

Quite recently, X-ray free-electron laser experiments for detecting fast dynamics of a protein at the atomic resolution have been announced. It is strongly expected that these experiments, with the help of femtosecond spectroscopy, may open a new era in revealing protein-folding mechanisms ranging from femtoseconds to seconds in the forthcoming decade.

B. Recent Progress in the Development of Models for Protein-Folding Simulations

In recent progress in protein-folding simulations, force fields for the all-atom model have been updated extensively. Although further refinements might still be needed to improve accuracy, most current force fields are capable of folding proteins in good agreement with experimental data, indicating that semiempirical atomic force fields are accurate enough to simulate protein folding. However, it is expensive computationally to produce statistically reliable trajectories of protein folding to reach a typical folding time scale, i.e., milliseconds, because the time step for MD is typically 1 fs, so that 10^{12} iterations of the integration are required. Generally, the accessible time scale traced by the laboratory-level computer resources might be several hundreds of nanoseconds, which is far from the timescale for protein folding.

To extend the time scale of all-atom MD simulations, many coarse-grained (CG) models have been proposed and widely applied to large biological systems. There are two main families of CG models: the elastic network models (ENMs) and the Go models. In the ENMs, each residue of a given protein is spatially coarse grained as a particle, i.e., one bead per residue, where the interactions between the CG particles are defined as collections of harmonic springs. If a pairwise distance between two CG particles is small enough, their interaction is modeled with a harmonic spring. In the Go models, the local and nonlocal contacts are distinguished and the nonlocal pairwise potentials are represented by a dissociative function using the Lennard-Jones potential. The merits of CG MD are speed and low cost compared with all-atom MD, so that one can compute long-time dynamics of huge systems. The main demerits of CG MD are its low accuracy and lack of precise time scale. Thus, the results obtained from the CG MD simulations should be carefully compared with experimental data for validation.

C. Recent Trends in Hardware

As recent trends in specialized hardware developments, many techniques have been designed to reproduce protein folding. One way to enhance the conformational sampling of protein folding is simply to extend the simulation time period of the all-atom MD simulations. As a long-time MD simulation of protein folding, the first milestone might be a supercomputer simulation performed by Duan and Kollman in 1998 of the protein folding of the 36-residue villin headpiece in explicit solvent. In this simulation, a microsecond-order all-atom MD simulation sampled a snapshot that has 4.5 Å root mean square deviation measured from the NMR structure. Recently, as an example of progress in specialized hardware, a significant improvement in the computational efficiency of all-atom MD simulations has been achieved by a development of a specialized machine called 'ANTON' by D.E. Shaw's group. They performed all-atom MD simulations of some typically fast-folding miniproteins such as ubiquitin (76 residues)

including explicit water, reaching the timescales of microseconds to milliseconds, resulting in reproductions of reversible folding and unfolding events as statistically reliable trajectories.

Along with specialized hardware, general-purpose graphics processing units (GPUs) and many-core architectures (Intel Xeon Phi) have frequently been used with all-atom MD simulation programs, because they are relatively cheaper than specialized hardware and useful for a variety of applications. In particular, many important algorithms have been implemented on GPU-based MD programs for accelerating all-atom MD, in which several orders of magnitude speedup over the CPU implementations have been achieved. Because the standard MD packages for biomolecules including AMBER, GROMACS, and NAMD have been implemented on GPUs, nowadays one can use them for long-time all-atom MD simulation of relatively large proteins.

D. Recent Progress in Conformational Sampling Methods

Before the emergence of ANTON, several enhanced sampling methods based on external biases were extensively proposed, where external perturbations are artificially imposed to promote the protein folding. These methods can be categorized into two types. The first approach is to sample transition pathways under the condition that two end-point structures, i.e., a set of reactant and product, are given *a priori*. The second category is to find a global minimum efficiently in the free energy landscape as the native state of a given protein, based on the accelerated dynamics without referring to the end-point structures. These important methods are briefly explained below.

For protein folding, the first approach might be convenient to reproduce folding events from an unfolded structure to the native structure of a given protein because the boundaries are fixed. For example, the transition path sampling method provides ensembles of transition pathways connecting a set of unfolded and native structures. As another example, the string method might be powerful in obtaining a relaxed folding pathway on a minimum free energy pathway (MFEP). In the string method, coarse-grained collective variables (CVs) describing the protein folding must be specified *a priori*. Based on the CVs, multiple images of an initial folding pathway are gradually relaxed to an optimal folding route on the MFEP. For the latter, replica exchange MD (REMD) and multicanonical MD (McMD) simulations are well-established methods, and are called generalized ensemble (GE) methods. In GE methods, the specifications of reaction coordinates (RCs), i.e., CVs, describing the protein folding are not required. As general RCs, temperature or the potential energy of a given protein are employed to perform the REMD and McMD. The ensembles generated by the GE can be reweighted to derive the Boltzmann ensemble at the target temperature. As examples of additional biased dynamics, targeted MD (TMD) or steered MD (SMD) provide sets of candidates of folding pathways with external restraints or forces for the native structure of a given protein. If the folding pathways generated by TMD or SMD have some hysteresis, the imposed restraints and forces might be inappropriate. As a self-updating biasing sampling method, meta-dynamics (MetaD) simulations have been widely used to reproduce rare events, including protein folding. In the MetaD, history-dependent external bias potentials along CVs have been imposed to reproduce the protein folding, leading to efficient folding into the native structure. One of the merits is that MetaD can simultaneously evaluate free energy differences among minima through single dynamics. However, a rather technical issue is how long one should continue the MetaD.

In any case, it might be difficult to restore details of the dynamics of protein folding from these methods, because all accelerated dynamics track trajectories with modified statistical treatments or with modified potentials, which are different from the real dynamics that are reproduced by naive long-time MD simulations by ANTON. In other words, the time series of detailed atomic trajectories are discarded in compensation for increasing the conformational sampling efficiencies. In this sense, it should be noted that these methods do not directly reproduce the dynamics of protein folding.

E. Importance of Robust Analysis Methods for Protein Folding

To extract the dynamics of protein folding, one might need analytical methods that are capable of reducing simulation data to their essential features without discarding physical insights. Nowadays, one can simulate the folding of relatively small proteins in explicit solvent at 100 ns per calculating day with GPU machines. These simulations provide long-time atomic trajectories as big data, however, and it is difficult to extract essential protein dynamics from them because of their high dimensionalities. For this problem, several analytical and numerical techniques in the fields of informatics and data analysis have been extensively applied, such as principal component analysis (PCA) and its variant, multivariate statistics (MS), time series data analyses, network-based models (NMs), and so on. The two former analyses/methods are used to find appropriate RCs that describe essential protein-folding dynamics, and the last one is called the Markov state model (MSM); these are well-established algorithms representing the first-order kinetics between a set of discrete states (microstates) projected onto a subspace spanned by the RCs. Once the appropriate RCs have been found, MSMs have been widely applied to yield the lifetimes of microstates by solving master equations for them, where conformational transitions among the microstates are represented by a transition matrix evaluated from the given trajectories. Because of the flexibility of MSMs, one must carefully confirm whether or not the kinetics obtained by the MSM correctly describe the protein-folding events by comparing the results with experimental evidence. Furthermore, a unique determination of the appropriate RCs is a nontrivial task, because it is difficult to use common CVs, for example those taken from PCAs, for reactant and product. Therefore, one must also carefully specify the appropriateness of RCs and check whether the analyses correctly explain the essential protein dynamics of interest.

F. Towards Protein-Folding Simulation in Cellular Environments

Most current protein-folding simulations assume that the protein folding occurs in a dilute aqueous solution. However, in practice, biological cells consist of many elements such as proteins, nucleic acids, lipids, metabolites, and ions, and the protein folding must be considered in these crowded environments that are significantly different from those typically encountered in experimental studies. Protein crowding appears to modulate the kinetic properties of the protein folding. Furthermore, crowded environments might shift the structural stabilities of native states after the protein folding. From the viewpoint of the effect of protein crowding, stability involves an entropic stabilization of the native state because of volume exclusion that is related to limits of the space for extended conformations, deriving compact and globular shapes that tend to be stabilized as native structures in the crowded environment. Theoretical studies with a hard-sphere model by Minton supported the stabilities derived by the excluded-volume effect. However, recent hydrogen-exchange NMR studies of several proteins in concentrated conditions and non-protein-crowder solutions showed that the structural stability of the protein depended strongly on the surrounding crowders, meaning that stabilities of proteins measured in dilute conditions are different from those for crowded (cellular) environments. Recent crowding simulations in explicit solvent reported by Feig *et al.* have supported these results and concluded that protein stabilities are affected by the surrounding crowder types, suggesting that the effect of crowding primarily depends on the nature of the protein–protein interactions with the surrounding crowder proteins. Therefore, the protein-folding process might be affected by the protein–protein interactions of the intermediates of the protein folding and shift away from the folding pathways in dilute solution. With our expanded computational resources, full atomic crowding simulations are feasible, but physically and computationally valid models that describe the protein folding under cellular environments are strongly desirable future work.

Abstract

Biophysical aspects of DNA and RNA are covered. A brief introduction into DNA and RNA chemical structure is given. Main helical structures of DNA and RNA are described: A, B, B', Z forms and parallel-stranded DNA. Special emphasis is given to a variety of functional RNA molecules. DNA topology, DNA supercoiling and DNA unusual structures induced by negative supercoiling (triplexes, cruciforms) are described. Theoretical models to study RNA and DNA are indicated. Nanostructures and nanodevices based on DNA and RNA are discussed and single molecule experiments with DNA are briefly covered.

Introduction

DNA and RNA together are known as nucleic acids. Their full names are deoxyribonucleic acid and ribonucleic acid, respectively. They play a crucial role in all living organisms because they are the key molecules responsible for storage, duplication, and realization of genetic information. They are both heteropolymeric molecules consisting of residues (nucleotides) of four types. Four RNA nucleotides are shown in Fig. 1. They consist of the phosphate group, sugar (called ribose) (these two elements are identical for all four nucleotides), and nitrous bases, which determine the type of the nucleotide. DNA nucleotides are very similar to RNA nucleotides. The main difference is that the right-handed OH group in sugar is replaced with just H (making deoxyribose). Three bases (A, G, and C) are the same for DNA and RNA. Only the fourth base is different: instead of uracil (U), DNA carries thymine (T) (see Fig. 2). The DNA chain is shown in Fig. 3.

In living nature, as is observed today, DNA plays the most important role because genetic information is stored and duplicated in the form of DNA in all living cells and organisms without any exceptions. Only in some viruses, which are not living creatures because they cannot reproduce themselves outside cells, the genetic information may be carried in the form of RNA molecules. A notable class of such viruses is retroviruses, which include many cancer-inducing viruses as well as HIV, the AIDS virus. A genetic message is “written down” in the form of a continuous text consisting of four letters (DNA nucleotides A, G, T, and C). This continuous text, however, is subdivided, in its biological meaning, into sections. The most significant sections are genes, parts of

Fig. 1 Chemical formulas of residues of RNA, i.e., of nucleotides. At the top are the pyrimidine nucleotides (U and C), and below, the purine nucleotides (A and G). Nucleotides within DNA differ in that, instead of the right-hand lower OH group, they simply have H. In addition, DNA, instead of the uridine nucleotide, includes the thymidine nucleotide whose top C—H group in the ring is replaced by the C—CH₃ group.

Fig. 2 Thymidine monophosphate is a thymine nucleotide that is part of DNA. The remaining three DNA nucleotides have similar structure, but each has a nitrous base of its own (the top group). These three bases (adenine, guanine, and cytosine) are identical in DNA and RNA (see Fig. 1).

Fig. 3 (A) The DNA single strand and (B) the Watson–Crick complementary base pairs.

DNA, which carry information about the amino acid sequence of proteins. Whereas DNA stores and duplicates genetic information, RNA plays a key role in its realization, that is, in the process of synthesis of a protein molecule in accordance with the nucleotide sequence of the corresponding gene.

This process consists of two major steps. First an RNA copy of the gene is made with the help of a special enzyme, RNA polymerase. The process is called transcription and the RNA copy of the gene is called messenger RNA (mRNA). The mRNA is an exact copy of the gene, in which all thymines (T) are replaced with uracils (U). In the second step, called translation, mRNA is used as a template for protein synthesis in a special cell machinery, the ribosome. Ribosome is a complex aggregate of special ribosomal RNA (rRNA) and a number of proteins. It translates the nucleic acid text into amino acid language. In so doing, it uses a special dictionary, the genetic code. In the process of translation, a very important class of additional small RNA molecules plays a crucial role. These RNA molecules consist of about hundred nucleotides and are called transfer RNA (tRNA).

In this article, an overview of the present knowledge of physical structures of nucleic acids is provided. The most important structural transitions, such as DNA melting and B–Z transition, are explained. Special attention is paid to the topological properties of DNA, which play a significant role in its functioning within the cell. Theoretical models, which are most popular in the field of biophysics of DNA and RNA are also overviewed. Recently emerged areas of DNA and RNA biophysics, such as single-molecule experiments and DNA/RNA nanostructures are also considered.

Structures of DNA and RNA

Traditionally, the structural versatility of nucleic acids had been considered as much narrower than that of proteins. This viewpoint fitted well “the division of power” between nucleic acids and proteins in present-day living creatures. The major function of nucleic acids is to store and reproduce genetic information while proteins perform an innumerable variety of reactions within the cell and are also its main construction blocks. The discovery of ribozymes (RNA molecules capable of catalytic functions) and of the remarkable versatility of the RNA structure completely changed the attitude toward the pivotal question of which type of major biopolymers, proteins or nucleic acids, had been the prebiotic molecule, forefather of the living cell. Earlier, everybody believed that only protein could fulfill this function. Now, the common view is that this should be the RNA molecule (the RNA World concept).

Major helical structures of DNA

In spite of enormous versatility of living creatures, and, accordingly, variability of genetic texts which DNA molecules in different organisms carry, they all have virtually an identical physical spatial structure: the double-helical B form discovered by Watson and Crick in 1953. Sequences of the two strands of the double helix obey the complementary principle. This principle is the most important law in the field of nucleic acids, and, probably, the most important law of living nature. It declares that in the double helix, A always opposes T and vice versa, whereas G always opposes C and vice versa.

B-DNA

It (see Fig. 4A) consists of two helically twisted sugar-phosphate backbones stuffed with base pairs of two types, AT and GC. The helix is right-handed with 10 bp per turn. The base pairs are isomorphous (see Fig. 3): the distances between glycosidic bonds,

Fig. 4 Schematics of (A) B-DNA and some unusual structures of DNA: (B) Z-DNA, (C) intermolecular triplex, (D) cruciform, (E) H-DNA, (F) G-quadruplex and its various folding modes.

which attach bases to sugar, are virtually identical for AT and GC pairs. Due to this isomorphism, the regular double helix is formed for an arbitrary sequence of nucleotides and the fact that DNA should form a double helix imposes no limitations on DNA texts. The surface of the double helix is by no means cylindrical. It has two very distinct grooves: the major groove and the minor groove. These grooves are extremely important for DNA functioning because in the cell, numerous proteins recognize specific sites on the DNA via binding with the grooves.

Each nucleotide has direction: if one treats sugar as a ring lying in the plane, then the CH_2 group will be above the plane (see Fig. 1). This carbon is designated as 5' whereas the carbon atom connecting the sugar to the next nucleotide in the polynucleotide chain is designated as 3'. In the DNA double helix, the two strands have opposite directions.

In B-DNA, base pairs are planar and perpendicular to the axis of the double helix.

Under normal conditions in solution, often referred to as "physiological" (neutral pH, room temperature, ~ 200 mM NaCl), DNA adopts the B form. All available data indicate that the same is true for the totality of DNA within the cell. It does not exclude, however, the possibility that separate stretches of DNA carrying special nucleotide sequences would adopt other conformations.

B'-DNA

Up to now only one such conformation has been demonstrated, beyond any doubts, to exist under physiological conditions. When three or more A residues in one strand (and, accordingly, T's in the other DNA strand) are met, they adopt the B' form. In many respects, the B' form is similar to the classical B form. There are two main differences: base pairs in B'-DNA are not planar (they form a kind of propeller with the propeller twist of 20°) and the minor groove in B'-DNA is twice as narrow as in B-DNA.

A-DNA

Similar to B-DNA, the A form can be adopted by an arbitrary sequence of nucleotides. As in B-DNA, the two complementary strands in A-DNA are antiparallel and form right-handed helices. Normal DNA undergoes transition from the B to A form under drying. In A-DNA, the base pairs are planar but their planes form a considerable angle with the axis of the double helix. In so doing, the base pairs shift from the center of the duplex forming a channel in the center.

Z-DNA

It presents the most striking example of how different from the B form the DNA double helix can be (Fig. 4B). Although in Z-DNA the complementary strands are antiparallel as in B-DNA, unlike in B-DNA they form left-handed, rather than right-handed, helices. There are many other dramatic differences between Z- and B-DNA.

Not any sequence can adopt the Z form. To adopt the Z form, the regular alternation of purines (A or G) and pyrimidines (T or C) along one strand is strongly preferred. However, even this is not enough for Z-DNA to be formed under physiological conditions. Nevertheless, Z-DNA can be adopted by DNA stretches in cell due to DNA supercoiling (see below). The biological significance of Z-DNA, however, remains to be elucidated.

ps-DNA

The complementary strands in DNA duplex can be parallel. Such parallel-stranded (ps) DNA is formed most readily if both strands carry only adenines and thymines and their sequence excludes formation of the ordinary antiparallel duplex. If these requirements are met, the parallel duplex is formed under quite normal conditions. It is right-handed but the AT pairs are not regular Watson--Crick ones, but rather so-called reverse Watson--Crick.

Some other sequences also can adopt parallel duplexes. For instance, at acidic conditions two strands carrying only C residues form parallel duplex consisting of hemiprotonated CC^+ base pairs (see the section "Quadruplexes"). However, any possible biological role of psDNA remains obscure.

RNA structure and function

Quite naturally, similarity between DNA and RNA in their chemical nature entails significant similarity in structures they adopt. RNA can also form the double helix with complementary base pairs AU and GC. However, the major RNA duplex conformation remains A-form rather than B-form.

In general, due to bulkier OH group in the sugar ring, the versatility of RNA duplexes is rather narrower than those of DNA.

In a cell, different types of RNA molecules (mRNA, rRNA, tRNA, etc.) exist as single strands. Of course, these strands are not unfolded, but fold into complex spatial structures. Mutually complementary stretches of the same molecules form numerous short

duplexes, which are a major structural motif of RNA molecules. Single-stranded regions form loops of different types. Sometimes very complex folding patterns, called pseudoknots, are met.

Spatial structure plays an important role in RNA functioning. For instance, rRNA organized in complex spatial structure forms a scaffolding to which numerous ribosomal proteins attach to form the functional ribosome. The elucidation of the full 3D structure of the ribosome by X-ray crystallography has been one of the major achievements of biophysics and structural biology. Spatial structure at tRNA molecules are specially designed to permit them to fulfill the central role in the realization of the genetic code. One part of tRNA carries the anticodon, a trinucleotide complementary to a codon (a trinucleotide corresponding to one amino acid in the genetic code), whereas the amino acid, which corresponds to the codon in the genetic code, is attached to the 3' terminus of the molecule.

More we learn about the living cell, more RNA molecules of different kinds emerge, which had been overlooked before and which proved to be extremely important. A totally new class of small RNAs was discovered at the turn of the century, which are involved in the RNA interference (RNAi) pathway and participate in the gene expression regulation on the level of mRNA. Most important of these small regulatory RNAs are small interfering RNAs (siRNAs) and micro RNAs (miRNAs). The RNAi pathway is present only in eukaryotes. Another groundbreaking discovery made already in 21st century was so-called CRISPR mechanism of bacterial immunity against bacteriophages. Here small ssRNA molecules, called CRISPR RNAs (crRNAs) or guide RNAs (gRNAs), recruit CRISPR associate (cas) endonucleases and guide them to the specific sites on dsDNA recognized by gRNAs via base pairing with one of two DNA strands. As a result, the cas protein inflicts the double strand break into target dsDNA. The CRISPR-cas mechanism discovered in bacteria has been converted into the revolutionary CRISPR-cas technology, which makes it possible to perform in vivo genome editing in eukaryotes, including humans.

DNA topology

DNA very often operates within the cell in the form of a closed circular molecule in which both strands form closed circles (Fig. 5). The physical properties and physiological behavior of closed circular (cc) DNA are different in many respects from those of linear DNA molecules. These differences stem from the fact that ccDNA acquires, as compared to linear DNA, a new fundamental feature, topology. There are two levels of DNA topology.

Knots of DNA

The double helix, as a whole, may form a simple circle (i.e., a trivial knot) or be knotted (see Fig. 6). Knotting of DNA may be conducted by random closure of linear molecules with "cohesive" ends (mutually complementary single-stranded overhangs). There are also different enzymes which do the job. The most important class of such enzymes is known as DNA topoisomerases II. The type of knot is the topological invariant, that is, it cannot be changed (converted to another type of knot) without breakage of both DNA strands. As a result, identical ccDNA molecules belonging to different knot types may be separated in gel.

Fig. 5 In a ccDNA, two complementary strands form a linkage of a high order.

Fig. 6 Knots.

DNA supercoiling

The two complementary strands in ccDNA are topologically linked with one another (see Fig. 5). The degree of linkage, which is designated as Lk , the DNA linking number, is a topological invariant, which cannot be changed with any deformations of the DNA strands without strand breaks. The Lk value is easily calculated as the number of times one strand pierces the surface placed on the other strand. If N is the number of base pairs in DNA and γ_0 is the number of base pairs per one turn of the double helix under given ambient conditions, then the difference:

$$\tau = Lk - N/\gamma_0 \quad (1)$$

is the number of superhelical turns in ccDNA under given conditions. If $\tau \neq 0$, then ccDNA cannot form a planar ring with the helical twist corresponding the γ_0 value. Either the helical twist should change or the DNA molecule as a whole should writhe in space. Actually, with $\tau \neq 0$ both things happen: the DNA adopts the writhe, and its twist changes. The distribution of energy associated with DNA supercoiling (i.e., with $\tau \neq 0$) between twist and writhe is determined by the torsional and bending rigidities, which have been measured with good accuracy. Supercoiling is also significantly affected by replication and transcription. DNA topology plays an extremely important role in DNA functioning.

Structural transitions and unusual structures

If negative supercoiling in ccDNA becomes too high, the bending and torsional degrees of freedom may become insufficient to accommodate the superhelical energy. Under these circumstances, the integrity of the DNA double helix breaks down at its most “weak” sites. These sites, which have the potential to adopt structures significantly different from B-DNA, can undergo structural transitions into unusual (non-B-DNA) structures.

DNA melting

On heating or under superhelical stress, the DNA complementary strands separate forming single-stranded loops. In case of linear duplex molecules, the process ends up, at a high temperature, with complete separation of the two strands. The process has been studied comprehensively both experimentally and theoretically and is known as DNA melting (the terms denaturation or helix-coil transition are also used in literature). AT pairs have significantly lower stability than GC pairs.

With increasing temperature, long DNA sections melt out. Melting of each such section is a cooperative, all-or-none phenomenon. However, melting of a long enough molecule becomes a series of such cooperative processes, each occurring at its own temperature (Fig. 7). Roughly speaking, sections more enriched with GC pairs melt out at higher temperatures. Thus, DNA melting is not a classical phase transition because two different “phases,” helical and melted, coexist with each other in one and the same molecule.

When two mutually complementary single-stranded DNA molecules are mixed, the process reverse to melting occurs. It is called renaturation, annealing or hybridization.

DNA melting is an exceptionally important phenomenon. It occurs in the cell when DNA replicates and when DNA polymerase “reads” the mRNA copy of the gene. Cycles of melting and annealing are utilized in the polymerase chain reaction (PCR) machines, which belong to the most remarkable tools of the current biotechnology revolution.

B–Z transition

Negative supercoiling favors the formation of Z-DNA most because, in this case, the maximal release of superhelical stress per 1 bp adopting a non-B-DNA structure is achieved. As a result, although under physiological conditions the Z form is energetically very unfavorable as compared with B-DNA, it is easily adopted in negatively supercoiled DNA by appropriate DNA sequences (with alternating purines and pyrimidines).

Cruciforms

Another structure readily formed under negative supercoiling is cruciform, which requires palindromic regions (see Fig. 4D). To form cruciform, a palindromic region should be long enough. For example, 6 bp long palindromes recognized by restriction enzymes do not form cruciforms under any conditions.

Fig. 7 Melting of DNA. This curve is also often called the differential melting curve. The curve was obtained for DNA that has the code name of ColE1 and contains 6646 base pairs.

Triplexes

Intramolecular triplex or H-DNA forms a special class of unusual structures, which are adopted under superhelical stress by sequences carrying purines (A and G) in one strand and pyrimidines (T and C) in the other, that is, homopurine–homopyrimidine sequences. The major element of H-DNA is triplex formed by a half of the insert adopting the H form and by one of two strands of the second half of the insert (Fig. 4E). Two major classes of triplexes are known: pyrimidine–purine–pyrimidine (YRY) and pyrimidine–purine–purine (YRR). Fig. 8 shows the canonical base-triads entering these triplexes.

Always two isomeric forms of H-DNA are possible, which are designated as H-y3, H-y5, H-r3, and H-r5 depending on which kind of triplex is formed and which half of the insert forms the triplex (see Fig. 4E).

Discovery of H-DNA stimulated studies of intermolecular triplexes, which may be formed between homopurine–homopyrimidine regions of duplex DNA and corresponding pyrimidine or purine oligonucleotides (Fig. 4C).

Quadruplexes

Of all nucleotides, guanines are most versatile in forming different structures. They may form GG pairs but the most stable structure, which is formed in the presence of monovalent cations (especially potassium), is G4 quadruplex (see Fig. 4F). G-quadruplexes may

Fig. 8 The structure of (A) pyrimidine (TAT and C⁺GC), and (B) purine (AAT and GGC) base triads of which the DNA triple helix is made. In YRY triplexes, the Y strand lying in the major groove of the duplex is parallel to the R strand of the Watson-Crick duplex and forms with it Hoogsteen pairs. In YRR triplexes, two R strands are anti-parallel to each other and are connected with each other via reverse Hoogsteen pairs.

exist in a variety of modifications: all-parallel, all-antiparallel, and others. As a result, G-quadruplexes are easily formed both inter- and intramolecularly, again with a variety of modifications. A remarkable variety of quadruplex structure was discovered for protonated cytosines. This structure, called i-motif, consists of two pairs of parallel stranded duplexes consisting of hemiprotonated CC⁺ base pairs. In the final structure, two duplexes are mutually antiparallel and CC⁺ base pairs from one ps duplex alternate with CC⁺ base pairs from the other ps duplex. The structure is stable only at acidic pH because protonation is necessary.

Bent DNA

For an arbitrary sequence, the minimum energy conformation of the DNA double helix corresponds to the straight DNA axis. However, there is a notable exception to this rule. If three or more A nucleotides are located in a row in one of the DNA strands, the corresponding regions adopt the B' structure. As a result, the DNA axis experiences a bend of 20° in such a region. DNA bending plays an important role in DNA functioning.

RNA unusual structures

Most DNA unusual structures have their analogs in the RNA world. Specifically, formation of triplexes was first demonstrated for artificial RNA chains. Solitary RNA base-triads are often met in tRNA structures. Triplexes are formed by mixed DNA–RNA hybrids and some of them are rather stable.

However, in general, studies of RNA unusual structures lag behind corresponding DNA structures because methods to study unusual structures are much better developed in the case of DNA than in the case of RNA.

Nanostructures and nanodevices from DNA and RNA

One of the most rapidly developing areas in DNA and RNA biophysics consists in using the remarkable ability of nucleic acid to self-assembly for creation of nanostructures and nanodevices. In so doing, virtually all unusual structures described above are extensively used: triplexes, quadruplexes, Z-DNA, etc., as well as the duplex. Specifically, a family of topological and pseudotopological nanostructures has been assembled as is shown in Fig. 9A–C. An example of a nanodevice (nanoactuator) is shown in Fig. 9D. By adding specially designed single-stranded DNA chains, the nanoactuator is transformed from the relaxed form shown in Fig. 9D to a straightened form in which the A strand is extended into a straight double helix.

A very ingenious method for making sophisticated DNA nanostructures has been invented, which makes it possible to create so-called DNA origami. Using special computer programs, DNA oligonucleotides are designed, which will bind to a long DNA molecule with the known sequence and fold it into the desired 3D structure. By this approach a huge variety of nanostructures are being created.

A special class of short ssRNA molecules, called aptamers, has been developed. These molecules are produced via special in vitro selection process, called SELEX, and they are selected on their ability to bind strongly to particular proteins. Aptamers find more and more applications.

Biophysical methods to study DNA and RNA

The whole arsenal of methods, which is traditionally used to study molecular structure, is applied to DNA and RNA. A leading position is occupied by X-ray crystallography, which provided us with a knowledge of details of the atomic structure of DNA and RNA. X-ray crystallography made it possible to solve the structure of the nucleosome, the main building block of chromosomes consisting of DNA and histone proteins, and of a major cellular machinery, ribosome, consisting of RNA and many proteins. The next method is proton NMR, which is especially valuable when biological molecules resist crystallization, a not uncommon problem with nucleic acids. An enormous body of data on the structure of DNA triplexes, quadruplexes, and various ribozymes was delivered by NMR. Electron microscopy (EM), cryo-EM and atomic force microscopy (AFM) have become indispensable in studying the DNA and its complexes with proteins. Most recently, a dramatic progress in single particle analysis of cryo-EM images has made this approach a method of choice in elucidation of structure of large nucleoprotein assemblies, like ribosomes. All kinds of spectroscopy methods, UV, IR, Raman, and CD are very useful in studying conformational transitions in DNA and RNA. A special role is played by various fluorescence methods, which find more and more applications not only in biophysical studies, but also in biotechnology. Below, specific methods, which have been specially developed in the field of DNA and RNA biophysics are discussed.

Theoretical models

As in the study of any important physical object, a number of simplified theoretical models of nucleic acids exist, different models being used to analyze different properties. Fig. 10 presents schematics of some of these models.

The DNA double helix may be treated as an isotropic elastic rod (Fig. 10A). In the framework of this model, the DNA molecule is described by only three parameters: bending, torsional rigidities, and the diameter. The model has proved to be extremely useful for analyzing hydrodynamics and other properties of linear DNA, when it behaves as a usual polymeric molecule. It has also provided a comprehensive theoretical treatment of DNA topology of both levels: knotting and supercoiling. More recently, the model has been extensively used for quantitative analysis of the force-extension curves for DNA in single-molecule experiments (see below).

A quite different, but also very successful, model treats the DNA double helix as consisting of base pairs of two types: closed and open (Fig. 10B). This is the helix-coil model, which explains all major features of DNA melting quantitatively.

The polyelectrolyte model (Fig. 10C) treats DNA itself just as a charged cylinder but allows for mobile counter-ions surrounding the double helix.

To predict the RNA structure, a simplified model of RNA folding is widely used (Fig. 10D).

Fig. 10 Theoretical models of nucleic acids: (A) elastic-rod model, (B) helix-coil model, (C) polyelectrolyte model, and (D) model of RNA folding.

Fig. 11 Stretching a single DNA molecule with optical tweezers.

Gel electrophoresis

Gel electrophoresis is a simple technique, introduced in the early 1970s, which truly revolutionized the biophysical studies of DNA and RNA and, subsequently, the whole field of molecular biology. All developments in this field in the past 40 years are connected, directly or indirectly, with the gel electrophoresis method. Gel electrophoresis has pushed aside ultracentrifugation as the method to separate nucleic acids.

Gel electrophoresis differs from electrophoresis in solution only in the nature of the medium in which molecules are separated in the electric field. In case of gel electrophoresis the medium is the gel, a polymer network. The most popular in the field of nucleic acids are gels made of polyacrylamide or agarose. Originally, the great advantage of gels in the separation of nucleic acids was discovered purely empirically. The understanding came later after some ideas of P-J De Gennes were borrowed from polymer physics, namely the notion of reptation of polymer molecules.

Single-molecule experiments with DNA and RNA

In recent years, remarkable progress in the application of the single-molecule techniques to DNA and RNA studies has been achieved. There are many different formats for single-molecule experiments. For example, a DNA molecule consisting of about 50 kbp is attached via one terminus to a pipette tip equipped with a streptavidin-covered polymer bead. Streptavidin is a protein, which binds very strongly to a small molecule, biotin. The DNA terminus is covalently tagged with biotin to be attached to the streptavidin-covered bead. The other terminus is also attached to the polymer bead, but the bead is not fixed. Then, optical tweezers are used to drag the free bead with the DNA attached to it. As a result, a single DNA molecule can be stretched in a fully controllable manner and the force created in the process can be accurately measured (see Fig. 11).

These experiments have allowed, for the first time, measurement of the force–extension curves of ds and ss DNAs and comparison of the curves with theoretical predictions. One of the important directions of these studies include isothermal melting of DNA and RNA duplexes under the external force. The influence of the force on the performance of major enzymes working on DNA and RNA (DNA and RNA polymerases) has also been studied. A very important feature of single-molecule experiments consists in the fact that they introduce a new variable on which DNA and RNA structure critically depend, the external force.

Abstract

DNA and RNA offer fascinating possibilities for the self-organization of complex patterns, which can be used in various combinations. Since this self-organization occurs at the nanometer scale, it can possibly offer ways for the creation of nanooptical or nanoelectronic devices. Therefore, the quest for conductivity of DNA or RNA has inspired a vast amount of experiments, which have led to a large number of diverse results. In the recent past, a coherent picture has emerged which describes charge transport along DNA or RNA in various environments. Based on this, electronic applications of these biomolecules have been developed.

Key points

- Electrical and electronic properties of DNA and RNA are reviewed.
- Theoretical models for understanding the electronic properties are discussed.
- Experimental techniques for measuring DNA and RNA electrically are presented.
- Experiments and theory on charge transport in DNA and RNA are reviewed.

Introduction

The electronic properties of biomolecules may lead to novel applications in the field of nanoelectronics, because self-organization of complex nanostructures can be encoded in the base sequence of the constituting molecules. Therefore, experimental and theoretical studies of such molecules will elucidate which applications can be targeted with such nanostructures. It is *a priori* not clear whether one might expect good charge conductance in DNA or RNA molecules or in ensembles composed of these molecules. This question thus triggered a large number of experiments in the late 1990s, which resulted in amazingly disparate results (Porath et al., 2000; Braun et al., 1998; Kasumov et al., 2001). It soon became clear that the reasons for the large variation of conductance values in DNA nanojunctions are given by the influence of the environment (Gutierrez et al., 2005) or the different conformation or base sequence of the DNA strands (Xu et al., 2004). Single-stranded DNA appears to be not conducting (Cohen et al., 2005) and sequences containing A-T base pairs are less conducting than sequences containing G-C pairs only (pG-pC DNA).

The complexity of the system makes understanding of the underlying charge mechanism rather difficult. Therefore a number of simplifying assumptions have been taken into account in order to describe the charge transport in DNA molecules. An overview of the models resulting in this approach is given in Section “Conductance in organic molecules.” The main challenge of contacting single DNA molecules for charge transport measurements arises from the nanoscale dimensions of the structures. In the past decades, the field of molecular electronics has developed a large number of techniques to achieve such contacts (Metzger, 2015). Some of these techniques have been successfully applied for measuring charge transport as well. In addition, techniques for contacting DNA molecules have been developed, which rely on special properties of the DNA. An overview of the contacting
